*12G10* The mAb 12G10 binds to the βA of $\beta_1$ integrins; binding is stimulated by Mn(II) or Mg(II), and inhibited by Ca(II) [53]. The affinity and binding of 12G10 is increased upon ligand (fibronectin or fibronectin-derived peptide sequence) binding to $\alpha_5\beta_1$, making 12G10 a prototypical ligand-induced binding site (LIBS) antibody. The MIDAS metal is required for high-affinity mAb binding since the binding to the MIDAS mutant D130A was comparable to the wild-type holoreceptor in the absence of cations; however, the MIDAS mutant was more sensitive to inhibition of 12G10 binding by Ca(II). The 12G10 epitope lies within residues 207–218 in the α2 helix βA, a region that is shared by other $\beta_1$ activation-sensitive antibodies. 12G10 is distinguished from other mAbs that bind to this region by the modulation of binding by divalent cations [54]. The divalent cation sensitivity is conferred by a unique contribution of the epitope formed from R-154 and R-155 in the α1 helix. While mutation of flanking residues (N-151, M-153, I-156) did not affect the binding of 12G10, mutation of either arginine residue reduces the binding by 65 and 30%, respectively (the binding of mAb to the double mutant is attenuated by >80%). There is, however, no effect of either single or combined arginine mutations on other activation-sensitive mAbs binding to the 207–218 segment. Since the arginine residues are structurally proximate to residues 207–218, they likely represent part of the 12G10 binding interface on the integrin, although an indirect effect on mAb binding cannot be excluded. Inhibition of ligand binding by 12G10 presumably occurs by blocking an obligate translational motion of the α1 helix that occurs during transition to the open βA. Significantly, the mAb24 epitope of $\beta_2$, which becomes exposed upon activation of Mn(II), or activating mutations, includes R-122 in the α1 helix, which may be sensitive to the same conformational change that occurs in the $\beta_1$ βA domain [55, 56].

*PAC-1* Ligand-mimetic antibodies to βA (specifically $\beta_3$) have been obtained, through hybridoma screening and phage display. The first such antibody identified, PAC-1 is an IgM (pentavalent) that binds selectively to $\alpha_{IIb}\beta_3$ on activated (i.e., adenosine diphosphate (ADP) stimulated), but not resting platelets [57]. The Fab of PAC-1 retains the same binding specificity, although the binding of the pentavalent form is tighter due to avidity effects [48]. Binding is inhibited by RDS peptide and in the absence of divalent cations. The H-CDR-3 of PAC-1 contains the sequence RSPSYY**RYD**GAGPYYAMDY. Binding of PAC-1 to $\alpha_{IIb}\beta_3$ is critically dependent on the central RYD; even the relatively conservative mutation D → E abolishes ligand binding. The molecular presentation of the RYD is also critical since inversion (RYD → DYR) also eliminates the functionality of the mAb. However, the central tyrosine can be mutated to a G (giving a canonical RGD sequence) without loss of affinity or specificity. This is significant since several other mAbs that recognized $\beta_3$ integrins with an RGD sequence show no such specificity between $\alpha_V$ and $\alpha_{IIb}$.

*OP-G2 and LJ-CP3* The mAbs OP-G2 and LJ-CP3 also bind to $\alpha_{IIb}\beta_3$ through an RYD in the H-CDR-3; however, unlike PAC-1, the two IgGs do not require preactivation for binding [58]. All three RYD containing mAbs use the same D gene (DSP 2.0 encoding YYRYD) and $J_H$ (JH4); the remainder of the CDR sequences are diverse with ~40% homology between each of the three VH sequences. The light-chain homology is higher with both OP-G2 and LJ-CP3 using the same VK segment ($V_{K5}$) and PAC-1 using the $V_{K1C}$ (~60% sequence conserved in the VK compared to OP-G2 and LJ-CP3). However, the D gene usage is not the sole determinant of integrin binding since mAbs HP20 and PCG1-1, neither of which binds to integrins, use the same D segment [59]. Like PAC-1, the central tyrosine can be replaced with a glycine with no change in specificity, affinity, or requirement for preactivation.

A prominent feature in the crystal structure of OP-G2 is the long, extended H-CDR-3 loop protruding away from the immunoglobin surface, ~12 Å from the common antibody–antigen recognition site. The RYD sequence is located at the tip of the protrusion; the absence of any defined cavity at the antigen-binding site suggests that the mAb interacts with $\alpha_{IIb}\beta_3$ by the extension of the loop into a binding pocket on the integrin. Superposition of the Cα of VH and fibronectin demonstrates that the conformation of the loop is similar to that of natural RGD containing ligands. The RYD sequence itself takes on two distinct conformations in

the crystal; in conformation 1 the critical aspartic acid is direct outward from the loop and may represent the ligand-binding conformation, while in the second conformation the Asp is bound to a solvent and may be the free solution conformation of the loop [60].

A high-resolution crystal structure has not been determined for LJ-CP3 or PAC-1, so it is not possible to conclusively describe the origin for the similarities and differences in activation based purely on structural constraints. However, the number and composition of the amino acid sequence flanking the central RYD are different in PAC-1 and OP-G2 and likely account for the difference in sensitivity to activation. Two H-CDR-3 chimeric derivatives of the RGD analogies of PAC-1 and OP-G2 were created around a central RGD sequence (PAC-RGD-OP and OP-RGD-PAC) and the binding specificity compared to the native sequences (OP-RGD-OP and PAC-RGD-PAC). Sequence N terminal to the RGD determined the activation selectivity (≥10:1) of the chimeric mAbs; PAC-RGD-OPG bound only to activated platelets while OPG-RGD-PAC bound equally well to active or inactive platelets [61].

Differences in the specificity for activation may be due to distinct contacts between the paratope and antigen. Alternatively, the specificity (or lack thereof) may arise due to constraints on the loop conformation that differ in the two mAbs, resulting in alternate presentation of the central RGD motif, as the N-terminal PAC-1 sequence is six residues as opposed to four for OP-G2 [61]. Difference in the length and composition could affect both the local conformation of the loop and the angle of its presentation with respect to the body of the immunoglobin [59]. The additional amino acids residues in PAC-1 may shift the RGD motif from the center of the CDR loop and move it closer to the antigen-binding face of the VH. Significantly, the binding of $\alpha_{IIb}\beta_3$ to peptides decorated on plastic beads was independent of activation state for peptides with long spacer arms but explicitly required activation for peptides with short spacer sequences [62]. Moving the central RGD off the center of the CDR loop would have a similar effect by lengthening the distance between the RGD and the binding site, imposing an activation requirement for mAb binding [61].

*Class II mAbs to the β I-Like Domain Generated by Phage Display* Ligand-mimetic mAbs to $\alpha_{IIb}\beta_3$ have also been obtained using phage display [63]. Differential subtractive selection was used to (separately) pan a pair of libraries ("natural" and "synthetic") as earlier described for $\alpha_M\beta_2$ [64]. The integrin was presented on two distinct backgrounds, ADP activated platelets and in a constitutively active form (G-F-F-K-R truncation mutant) on the surface of CHO cells, to eliminate binding to cell-type-specific proteins. Negative selections were performed using nonactivated platelets and wt–$\alpha_{IIb}\beta_3$ expressed in CHO cells. Elution of bound phage from cells was performed either using a nonselective low pH protocol (which dissociates phage scFv from target regardless of specificity) or saturating concentrations of blocking mAb c7E3. Using these protocols, two nonactivation-specific and six activation-specific clones were identified. Based on analysis of the CDR sequences of the recovered clones, it was determined that competitive elution did not improve the diversity of recovered scFv over what is obtained from low-pH elution both in the natural and synthetic libraries. Almost all activation-specific scFv recovered have an RXD sequence (including RGD). However, the binding of each of these antibodies was weak, possibly due to suboptimal selection due to restricted diversity (only in H-CDR-3).

A secondary selection was thus performed using a sublibrary with the randomization in the sequence in L-CDR-3. The panning strategy was modified to improve the diversity and affinity of the recovered clones. The depletion step was eliminated, smaller numbers of cells were used for panning (to promote competition between members of the library for a smaller number of binding sites), and the elution protocol included recovering phage during addition of increasing concentrations of the small-molecule inhibitor eptifabitide. Thirty clones were randomly selected using this protocol. Almost all were activation specific with affinity comparable to the clones obtained using the natural library. Analysis of the clones did not reveal preferential enrichment of particular sequences in L-CDR-3, although the average length of the L-CDR-3 (~10 aa) was shorter than the original framework L-CDR-3 (13 aa).

Three clones were selected for further characterization. The $IC_{50}$ of binding of fibrinogen to ADP-activated platelets of clones from the primary synthetic library (with an RSD sequence) was > 50 μg/mL, while a clone from the VL diversified library (also having an RSD sequence) inhibited with an $IC_{50}$ of 1.2 μg/mL clearly demonstrating the utility of diversity in the L-CDR-3. By comparison, the clinically used mAb c7E3 (abciximab) has an $IC_{50}$ of 0.75 μg/mL but reduced conformational selectivity. The aggregation of platelets by ADP, thrombin, or collagen was inhibited to similar extents by 15 μg/mL of each mAb and c7E3. In addition, the binding of each of the ligand mimetic scFv did not induce exposure of the LIBS epitope 145, which is associated with thrombocytopenia. Finally, mapping using both human mouse chimeras and alanine point mutations demonstrated that the mAbs bound at an interface that overlaps with the fibrinogen-binding site.

A similar approach was undertaken to the identification of a fully human, ligand-mimentic $\alpha_{IIb}\beta_3$ mAbs using a naïve Fab library derived from human bone

marrow cDNA (from heavy-chain DP-47) and an synthetic H-CDR-3 with a central RAD sequence and all 20 amino acids permitted at the 6 flanking residues (3 per side) [65]. The heavy chain was initially paired with the light-chain DPK-26 (κ). The Fabs were obtained in 7 rounds of panning on purified human αIIbβ3. Additional selections were performed using secondary libraries assembled with light-chain shuffling using both Vκ and Vλ sequences obtained from human bone marrow DNA, shuffled onto the heavy chain obtained in the primary selection. Ten clones with the highest affinity [as determined by phage enzyme-linked immunosorbent assay (ELISA)] were sequenced. Nine of 10 formed a disulfide constrained loop and shared the central sequence motif V(V/W)CRAD(K/R) RC (sequence number 10 was TSHRADRRE). Four of the 6 clones contained the original light chain while the remainder of the light chains were derived from the naïve chain shuffled library.

Each of the 10 Fabs showed specific binding to $\alpha_{IIb}\beta_3$ with no cross-reactivity to $\alpha_V\beta_3$, $\alpha_5\beta_1$, and $\alpha_V\beta_8$, both as purified proteins and integrins expressed on cell surfaces. Using a competitive ELISA, each of the 10 Fabs was able to inhibit the binding of purified, immobilized αIIbβ3 to fibrinogen. The $IC_{50}$ of the tightest binding Fab was determined to be $8.0 \times 10^{-8}\,M$ by comparison to abciximab ($9.0 \times 10^{-8}$.) The $K_D$ of the Fab $\alpha_{IIb}\beta_3$ interaction, determined by competitive ELISA, was $3.3 \times 10^{-9}\,M$ while that of abciximab was $1.1 \times 10^{-9}\,M$. The Fab also inhibited platelet aggregation (stimulated with 20 μ*M* of ADP) at a comparable level to abciximab ($EC_{50}$ 60 n*M* or 30 μg/mL versus 45 n*M* or 22.5 μg/mL).

## 4 CONFORMATIONALLY SELECTIVE MAB AS THERAPEUTICS: PROGRESS AND PROSPECTS

The use of conformationally selective mAbs as therapeutics is based on two premises: (1) nascent binding epitopes become exposed (or occluded) upon integrin and activation and (2) pathological versus physiological epitope exposure can be kinetically distinguished by the sustained signaling associated with disease states, which results in constitutive epitope exposure, unlike the transient upregulation of integrin activity observed in normal physiology [12]. Although the first postulate has been conclusively demonstrated, additional studies must be performed to conclusively validate the second.

Blocking protein–ligand interactions and drug targeting/delivery to specific cell types (i.e., activated but noninactive lymphocytes) are the two principal clinical applications of mAbs. One outstanding question is which class of epitope is most appropriate to use for each potential application. In this section, we review each application of activation-sensitive mAbs and discuss both the progress made and critical issues to be resolved for future therapeutic applications.

### 4.1 Selective Inhibition of Activated Integrins

Disrupting protein–ligand interactions is perhaps the most important and straightforward therapeutic application of mAbs. To date, all therapeutic mAbs block protein–ligand interactions without conformational selectivity. Improved pharmacokinetics and lower iatrogenic effects may be obtained when only the disease-active subset of integrin–ligand interactions is disrupted.

Although there have been no clinical studies on the use of blocking conformational selective mAbs, in vitro and in vivo studies using mouse models have offered compelling support for their potential [66]. A major limitation of existing antithrombosis agents that function as αIIbβ3 inhibitors is the tendency to prolong bleeding via nonselective binding to activated and inactive platelets. MA2, an anti-$\alpha_{IIb}\beta_3$ identified by phage display, was shown to block the adhesion of activated, but not inactive, $\alpha_{IIb}\beta_3$ expressed on CHO cells and platelets to immobilized fibrinogen under flow (in a parallel-plate flow chamber apparatus). The platelet function analyzer (PFA-100) assay (an in vitro human bleeding time assay) was used to compare the effect of c7E3 (abciximab) and MA2 on closure of human whole blood in cartridges sealed with epinephrine/collagen- or ADP/collagen-coated membranes. Despite the ability to block binding to immobilized and soluble fibrinogen, MA2 (but not c7E3) did not prolong the time for closure, even at relatively high concentrations of mAb (10 μg/mL).

MA2 does not cross-react with murine $\alpha_{IIb}\beta_3$, precluding the ability to use in vivo models of thrombus formation to validate the conformational selective strategy. However, mAb SCE5, obtained in a parallel phage display screen, does cross-react with human and murine $\alpha_{IIb}\beta_3$ and was used for in vivo studies [66]. Thrombus formation was induced by ferric chloride and the occlusion time measured using a nanoflow probe. Since (nonconformationally selective) mAb c7E3 also does not cross-react with murine $\alpha_{IIb}\beta_3$, it was not possible to directly compare the use of nonselective and selective mAbs. Instead, direct comparison of thrombus remediation and bleeding time prolongation was made between SCE5 and two clinically used integrin blocking agents, eptifabtide and tirofban. Treatment with mice administered ferric chloride with SCE5 decreased the thrombus occlusion time comparable to that obtained with the two approved drugs. However, unlike the small-molecule antagonists, there was no extension of the bleeding time, as measured both by two standard measures, the tail

transfection method and incision methods. This study was the first to demonstrate the superiority of conformationally selective therapy in remediation of a specific disease due to the reduction of pernicious side effects.

### 4.2 Selective Drug Delivery Targeting Activated Integrins

Targeted drug delivery describes the use of a specific ligand (either authentic ligand or antibody) conjugated to a drug molecule to mediate specific drug delivery to cells bearing the receptor with the appropriate specificity for the ligand [67–69]. The conjugation can be direct (covalent or noncovalent) or indirect (with drug encapsulated in a ligand-coated lipid vesicle). Ideally, the ligand should promote both accumulation and uptake (internalization) of drug. Since drug delivery is selective to cells requiring remediation, targeted drug delivery vehicles have two (related) advantages over passive delivery: (1) improved pharmacokinetics, since drug concentrations can be limited due to the restricted number of cells that uptake drug and (2) lower probably of systemic toxicity. Targeted drug delivery systems can be used to delivery a wide variety of drugs including catatonic (chemotherapeutic agents), radio nucleotides, and nucleic acids for genetically mediated therapy.

Genetically mediated therapy (*gene therapy*) is defined as a broad repertoire of techniques used to modulate the effect of a specific gene (typically one involved in disease) via the application of exogenous nucleic acids. Despite the large number of potential methods and applications of gene therapy, the technique can be divided into two classes: gene knockdown and gene replacement. In the case of the immune system, however, many receptors are present on both inactive and activated cells and selective targeting remains challenging. As described below, scFv can be used to enhance the selectivity of gene therapy for activated leukocytes without perturbing the majority of quiescent, unaffected cells.

*RNA interference (RNAi)* is the sequence-specific posttranslational gene-silencing mechanism mediated by double-stranded RNA (dsRNA) with sequence complementarily to a target gene (Fig. 4A) [70, 71]. RNAi is conserved in a wide range of organisms and functions as a part of the innate host defense against viruses and the mobilization of transposable genetic elements. Long dsRNA produced by replicating virus, endogenous micro-RNAs, or aberrant transgenic transcripts are processed by an RNAseIII-like enzyme (Dicer) into smaller, 21–25 mer dsRNA, referred to as small interfering RNA (siRNA). The siRNAs are subsequently unwound and assembled onto the RNA-induced silencing complex (RISC) that uses the siRNA as a guide to target mRNAs and direct their subsequent degradation.

RNAi can be achieved either by expressing siRNA precursors such as short hairpin RNA (shRNA) with viral vectors or by directly incorporating synthetic siRNAs into the cytoplasm of cells. The use of synthetic siRNAs as small-molecule drugs for gene silencing avoids clinical safety concerns associated with viral vectors. RNA interference can be activated by introducing synthetic short double-stranded RNA fragments, termed small interfere siRNAs into cells to silence genes bearing complimentary sequences. RNA is a powerful tool used to evaluate the role of specific genes in cellular and disease processes that also holds great promise for therapeutic remediation of metabolic, degenerative disease, viral infections, and cancer, as well as inflammatory diseases. The discovery that introduction of exogenous 21–25 mer siRNAs into mammalian cells leads to the degradation of the homologous target mRNAs without provoking interferon response cells has opened up a new avenue to utilize synthetic siRNA as a drug.

While cell-specific delivery can be obtained using direct or indirect conjugation of siRNA to antibody or ligand, only a small fraction of leukocytes are activated during inflammation, and it is desirable to selectively target this subpopulation for anti-inflammatory therapy. Peer and co-workers used an *antibody protamine fusion* approach [13, 72] to deliver siRNA selectively to activated leukocytes. A highly charged protamine moiety, genetically fused with an scFv appropriate of desired selectivity, binds to synthetic, negatively charged siRNA. The antibody guides the RNA to its target and promotes its uptake, via receptor-mediated endocytosis (Fig. 4A). As the conversion of $\alpha_L\beta_2$ integrin to the active conformation is a highly sensitive marker of activated leukocytes, the active conformation-selective mAb AL-57 was utilized to preferentially deliver siRNAs to aberrantly activated leukocytes. Peer et al. [13] used the scFv derivative of mAb AL-57, fused at the N terminus to the protamine fragment (AL-57-PF), to silence candidate genes only in activated leukocytes that express the active conformation of integrin $\alpha_L\beta_2$ , present in a larger population of inactive cells (Fig. 4B). In a proof-of-concept experiment, Peer et al. [13] were able to silence the *Ku-70* gene selectively in activated, but not unstimulated, leukocytes (Fig. 4B). Furthermore, Peer et al. [13] used siRNA against the *cyclin-D1* gene to selectively suppress proliferation in activated lymphocytes. In contrast, TS1/22-PF, which binds to $\alpha_L\beta_2$ integrin in a conformation-insensitive manner, delivered siRNA equally well to resting and activated leukocytes. These experiments were the first to demonstrate that a conformationally selective mAb fragment could

**Figure 4** Application of the active conformation-selective integrin antibody to siRNA delivery specific to activated leukocytes. (A) Receptor-mediated intracellular delivery of siRNA by scFv-protamine fusion protein (scFv-PF) and subsequent induction of gene silencing. ScFv-PF:siRNA complexes are directed via scFv to the target on the cell surface. Bound scFv-PF:siRNA complexes are internalized via receptor-mediated endocytosis, releasing siRNAs to the cytoplasm (potentially though an escape from the endosome). In the cytoplasm, siRNAs incorporated into RNA-induced silencing complex (RISC) leads to the cleavage of target messenger RNAs, inducing gene silencing. Inset: scFv-PF: protamine, a positively charged protein that binds to negatively charged siRNAs, is linked at the C termini of the scFv. (B) The active conformation-selective LFA-1 mAb AL-57 can be used to deliver siRNAs to induce gene silencing only in activated cells in mixed population. CMTMR (fluorescence dye)-labeled activated cells, expressing high-affinity LFA-1, were co-cultured with nonactivated (unlabeled) cells expressing low-affinity LFA-1. Three days after delivery of 1 nmol siRNA to Ku70, a reference protein, the co-cultures were analyzed. Whereas TS1/22-protamine fusion protein-delivered siRNAs silence Ku70 in both activated and nonactivated cells (panel C), AL-57-protamine fusion protein delivered siRNAs silence only the labeled activated cells (panel D). (This figure is modified from [13].)

be use to obtain modulation of gene expression and cell function in a therapeutically relevant context.

AL-57 does not cross-react with murine $\alpha_L\beta_2$. To demonstrate the ability of AL-57-PF to selectively silence gene expression in vivo, severe combined immunodeficiency (SCID) mice were engrafted with human erythroleukemia K562 cells stably transfected with wild- type (WT) and high-affinity (HA) $\alpha_L\beta_2$. After intravenous (I.V.) injection, the K562 cells formed small nodules in the mouse lung. Five days after injection, Cy3-conjugated siRNA complexed with AL-57-PF or TS1/22-PF was injected into the tail vein. At 5 h postinjection, the lung tissue was recovered and analyzed by FACS. TS1/22-PF delivered siRNA equally well to both WT and HA $\alpha_L\beta_2$-expressing K562 cells, while AL-57-PF delivered siRNA only to cells expressing the HA $\alpha_L\beta_2$-expressing K562 cells. Additional experiments will be required to demonstrate selective binding in a more authentic context (i.e., selective delivery to activated murine lymphocytes in an inflammation model). However, as there are no murine activation-specific $\beta_2$ mAbs, this must await development of the appropriate reagents.

Despite the promise of conformationally selective mAbs as therapeutics, a number of critical issues remain unresolved. Possibly the greatest bottleneck is the relative paucity of conformational selective antibodies for laboratory animal species, specifically rodents but also

pigs, dogs, and sheep. There are numerous, well-characterized animal models of human disease, including autoimmune diseases, cancer, susceptibility to bacterial infections, and transplantation. These would be ideal systems to investigate both basic integrin biology and the potential for conformational selective therapeutic remediation. Although great progress has been made in understanding the mechanism of integrin activation, the in vivo environment is much more complex with multiple competing (and overlapping) signaling pathways and ligands. Little is known about the mechanism by which integrin becomes activated in vivo, what is the spatiotemporal population of activated integrin in normal physiology, and how it differs in disease states. For ethical and practical reasons, these questions can clearly not be addressed using antihuman antibodies. Fortunately, the sequence for integrins from many laboratory animals have been published, and it should be possible to express cell surface and purified nonhuman integrins as the bait for antibody library selection. With these reagents in hand, it should be possible to address some of the most critical questions in the development of conformational selective mAb therapy.

## 5 APPENDIX

### 5.1 Overview of Monoclonal Antibodies

Antibodies are four-chain glycoproteins organized as a disulfide bonded homodimer of a disulfide-bonded heterodimer of one heavy (H) and one light (L) chain [stoichiometry $(HL)_2$] [73]. Both H and L chains are built from immunoglobulin fold (Ig) domains. There are five classes of H that differ in body tissue distribution, effector function, the position of disulfide bonds, interdomain flexibility, and number of Ig domains: IgA, IgD, IgE, IgG, and IgM. There are two classes of L, κ, and λ. Each antibody pairs one specific H chain with one L chain; there are no (naturally) occurring mixed H or L heterodimers. The IgG class has the highest concentration is serum (~14 mgs/mL), the highest circulating half-life (~21 days), and is the most clinically relevant.

There is (relatively) little sequence variation in the IgC domains within a given family. By comparison, there is extensive sequence variability in the IgV domains. Most of this variability (in both VL and VH) is concentrated in three loops [complementary determining regions (CDR) 1–3]. The specificity and affinity of antibodies for antigen is largely determined by the sequence and structure of the CDR loops. Interspersed between the CDR loops are the framework regions (FR 1–4) that maintain the structural orientation of the adjacent CDR regions. In the three-dimensional structure of the antibody, the six CDR loops are spatially proximate and form the binding interface with the antigen. The *paritope* is the set of amino acids on the antibody that contact the antigen (at the epitope). The hypervariable H-CDR-3 is not only the most variable in sequence but also in length, ranging from 6–14 aa, and generally contributes the most energetically significant antigen interactions to the interface.

The four N-terminal Ig domains preceding the hinge (VL-CL, VH-CH1) form the univalent *Fragment antigen binding (Fab)*. Fab fragments can be prepared by digestion of intact IgG with the cysteine protease papain which cleaves on the amino side of the disulfide bond; the second product is the *fragment crystallizable (Fc)* containing the CH2–CH3 domains, which interact with proteins in the activation of innate immunity.

The *Fv (fragment variable)*, the noncovalent dimer of VL and VH, is the minimal unit of antigen-binding specificity of (most) antibodies. Despite an extensive interface between the two domains, the heterodimer is relatively unstable and subject to dissociation on prolonged incubation. This technical restraint is overcome by the single-chain fusion of heavy- and light-chain variable domains (scFv) joined by a linker of 12–16 amino acid residues to span the 35–40 Å junction between the N and C termini of the two variable domains [74]. Linkers of various design have been used, although the most common are the trivial $(G_3S)_3$ and $(G_3S)_4$. The scFv can be assembled in two orientations VH–linker–VL and VL–linker–VH; generally both orientations are functional, although for some antibodies one orientation retains higher binding activity than the other. The small size of the scFv (ca. 20 kDa) is ideal for a conformation-specific binding reagent since steric interactions outside the binding epitope are minimized. Furthermore, the scFv is monomeric (circumventing avidity and cross-linking, which make quantitative analysis of binding problematic) and lacks the biological activity of the Fc region. However, for some applications, the avidity effects of multimerization may be desirable. Multimers of scFv can be obtained by altering the length of the linker between VH and VL or engineering multiple VH and VL sequences on a single DNA transcript [75, 76].

Unlike the Fab fragment, there is no ready preparative technique for obtaining scFv from intact antibodies, and it is necessary to either engineer the requisite gene de novo or screen a microbial library of scFv using bait antigen (vide infra). A novel cDNA encoding an scFv can be generated in four steps if the B cell (or B-cell derivative) that expresses the antibody is available:

1. RT-PCR of the antibody-expressing cell using degenerate primer sets that cover the appropriate

species heavy- and light-chain antibody repertoire.
2. Cloning and sequencing of the VL and VH domains.
3. Overlapping extension PCR to create a synthetic DNA that combines the VL and VH via an appropriate linker.
4. Cloning into an appropriate expression vector that includes a signal sequence and affinity tag for purification.

The relatively small size and limited number of disulfide bonds in the scFv permits the use of *Escherichia coli* periplasmic expression vectors to obtain high-level expression of correctly folded scFv. A $(His)_6$ tag is typically appended to the C terminus of the scFv to permit facile affinity purification using commercially available Ni(II) resins.

***Origin of Natural Antibody Diversity and Affinity*** The human immune system is capable of expressing at least $10^{11}$ antibodies with distinct specificity. Five mechanisms account for the remarkable size of the immune repertoire [1]. First, antibody heavy and light chains are combinatorially assembled from (distinct) multiple gene segments. The variable light chain is obtained by combining 1 of 40 Vκ or 1 of 30 Vλ segments (of 95–101 aa) with 1 of 5 Jκ or 1 of 4 Jλ segments (joining segments of up to 13 aa link the variable region to the constant domain). The heavy chain is built from 1 of 65 $V_H$ segments linked to 1 of 27 diversity (D) segments that are linked to 1 of 6 $J_H$. Second, in 5% of antibodies of a D–D fusion gives rise to a long H-CDR-3. A third source of diversity is the pairing of any one assembled light chain with any heavy chain. The enzymes that assemble the individual chains create a fourth source of diversity (in H-CDR-3) by adding or subtracting nucleotides during the assembly process. Finally, *somatic hypermutation* is the process whereby a large number of point mutations occur in the variable regions of both heavy and light chains of a single antibody, giving rise to many variants with differing affinity for antigen. B cells expressing the highest affinity antibodies are most likely to survive and become antibody-secreting cells. The combined process of somatic hypermutation and selection is known as *affinity maturation*.

Most laboratory antibody reagents and therapeutic agents have been obtained using *immunization–hybridoma technology* [77]. Mice produce a robust immune response following immunization with many protein antigens. A major difficulty in obtaining monoclonal antibodies of defined specificity following immunization is the inability to culture B cells. This limitation is overcome fusing spleen cells from an immunized animal with immortalized, non-antibody-producing myleoma cells to produce a *hybridoma*. The myeloma cell line is deficient in the enzyme hypoxanthinephosphoribosyltransferase (HPRT) and will not grow in media containing aminopterin. Spleen cells can use hypoxanthine and thymidine for RNA precursor synthesis. Fusion of the spleen cells with myeloma confers upon the hybridoma the ability to grow in aminopterin, allowing hybridoma cells to be selected from a mixture with unfused myeloma cells. The antibody that is secreted from monoclonal B cells is then screened for binding to the designed antigen. Care must be taken to ensure that the antigen is injected in the native state if conformation-sensitive antibodies are desired; isolated membrane fractions containing the protein are ideal for this purpose. Xenogenic antibodies that are intended for therapeutic application must be partially or fully humanized to avoid a human–antixeno (generally murine) response [78]. Humanization involves the grafting of all or part of the variable domains of an antibody onto a purely human framework or constant regions, followed by additional modifications that may be required to restore the affinity or specificity of the mAb.

### 5.2 Antibody Display Libraries

*Microbial surface display* of antibody libraries is an alternative to conventional immunization–hybridoma protocols for the isolation of new immunoaffinity reagents (Mondon et al., 2008). Antibodies with the desired selectivity are isolated by "panning" the library with desired antigen, retaining those that express favorable binding properties and rejecting non-binding and low-affinity clones. As the phenotype and genotype are "linked" by simultaneous presence on the particle, the DNA encoding the desired antibody can be recovered and used to obtain soluble protein for the desired application.

*Phage Display* is the most commonly used technique for the selection of affinity reagents from preexisting peptide and protein-fragment libraries [79, 80]. Filamentous bacteriophage (such as fd, f1, and Pf1) are single-stranded DNA viruses composed of ~2700 copies of a major coat protein (pVIII) encapsulating the single-stranded DNA (ssDNA) genome in a tube 1 μm by 6–7 nm. Approximately five copies of minor coat proteins pIII and pIX are located at opposite ends of the protein capsid.

Proteins (i.e., scFv and Fab) can be expressed in native form as fusions to the pIII protein where they are displayed on the surface of the phage. Libraries of scFv or Fab with sequence diversity in the CDR loops can be constructed by cloning the appropriate DNA into a

*phagemid vector*, which includes the packaging sequence for incorporation into the phage particle. An scFv or Fab library can be built using three sources of immune DNA [81]. The most unbiased source of DNA is obtained from the spleen, lymph nodes, or lymphocytes of laboratory animals or humans. When selection of antibodies against a particular antigen is desired, the animal can be pre-immunized to appropriately bias the immune repertoire. Finally, purely synthetic CDR sequences of defined length can be grafted onto standardized framework backbones. In a synthetic library, diversity is limited to selected positions that are hypervariable and/or participate at high frequency in the paratope of characterized antibody–antigen interactions. This approach maximizes the possibility of identifying an antibody that interacts with antigen in a relatively small library at the cost of not obtaining the highest potential affinity binders available in a more complex library. Transformation of the pool of vector DNA into the appropriate bacterial host (typically *E. coli*) is the final step in assembly of the library.

To obtain the desired affinity reagent, the library must be expanded and panned [82]. ScFv- (or Fab-) bearing phage are produced when the library cells are infected with a *helper phage* that carries the DNA for proteins required for phage synthesis and assembly. The desired antigen is immobilized, either randomly on plastic or in a given orientation (using affinity tags such as biotin - streptavidin ) and exposed to the phage library solution. After brief washing, only antigen-binding phage remain bound and are collected. The recovered pool of phage is used to reinfect bacterial cells. Each round of panning enriches the population of phage with specificity for a given antigen. The use of moderately biotinylated bait avoids protein denaturation that occurs upon binding plastic and is preferable when conformationally selective mAbs are desired.

An alternative source of bait is proteins in their native environment (i.e., in intact cells or cell membrane preparations) where the protein most likely maintains the native conformation and retains functionality. However, cell membranes contain many antigens, and nonspecific/off-target binding of phage is likely to occur, lowering the stringency of the screening protocol. Panning against the protein antigen expressed on two distinct cell line backgrounds (i.e., endogenous protein in T cells and CHO cell transfectants) increases the specificity of the selection protocol.

***Affinity Maturation*** Generally, it is desirable to obtain antibodies with the highest affinity to their cognate antigens. The affinity of library-selected antibodies is limited by the relatively small (by comparison to the immune system) diversity in the sequence and structure of the CDR. However, even mAbs selected by immunization have a wide range of affinities that may be insufficient for therapeutic application. The affinity can be further improved using in vitro affinity maturation and selection [83]. To affinity mature an mAb, it is necessary to diversify the sequence and structure of one or more CDR loops. The most straightforward approach is to use error-prone PCR to introduce one or more mutations into the cDNA encoding the antibody fragment (Fab or scFv). However, this process is relatively nonselective and inefficient (mutations are equally dispersed through the sequence instead of being targeted to key antigen-binding positions) and the bias of the error-prone polymerase does not necessarily match the optimal use of amino acids at key positions in the CDR sequence. A technically more challenging—but generally useful approach—is use overlapping extension PCR to reconstruct one or more CDR sequences using degenerate oligonucleotides with random sequences at positions found to vary in naturally occurring high-affinity antibodies [84]. If the paratope or crystal structure of the mAb–antigen complex is known, this approach can also be used to bias the randomized positions toward those that make favorable contacts with the antigen. Finally, the affinity can be improved by chain shuffling, pairing a library of light-chain domains with a heavy chain from the original selection [85].

***Antibody Humanization*** mAbs obtained from murine (or other species) hybridomas are immunogenic in humans. Even libraries assembled from purely human sequences are potential immunogens due to the novel sequences in the CDR loops that appear foreign to the immune system. For therapeutic applications, it is necessary to reduce or eliminate the xenogenic features of the mAb to avoid rapid clearance and a systemic inflammatory response [78]. A "foreign" mAb can be humanized by either (1) grafting the CDR loops from the murine mAb onto a human framework or (2) replacing surface residues (those most likely to provoke an immune response) with those found commonly in human mAbs . However, the binding affinity and specificity of the engineered mAb are not necessarily maintained. It is generally necessary to include one or more xenogenic framework mutations that contribute to the structure of the CDR loops into the humanized mAb. The affinity and specificity of the novel mAb may require reoptimization using phage display and affinity maturation.

# PAIN MANAGEMENT MARKET OVERVIEW

Anita Holdcroft
*Imperial College and Chelsea and Westminster Hospital, London, England*

## 1 INTRODUCTION

Worldwide an estimated one and a half billion people repeatedly endure moderate to severe pain. However, pain relief is not restricted to this population because pain is often of short duration. Both acute and chronic pain are associated with disability and distress that reduce quality of life. The International Association for the Study of Pain (IASP) has issued definitions (Table 1) and a classification of pain states based on temporal, site, and disease patterns [1]. The American Pain Foundation in 2002 through a Mason–Dixon Poll identified that more than 50 million Americans (18% of the total population, and set to increase to over 100 million in a decade) suffer chronic pain, thus making pain symptoms appear to be of epidemic proportions (http://www.painfoundation.org/page.asp?file=Library/PainSurveys.htm; accessed July 28, 2006). For example, 49% of 625 respondents had pain that varied from mild (31%), moderate (43%), moderate/severe (18%) to severe (7%), and of this group with pain, 40% of people experienced pain almost every day.

The definition of pain has recognized shortcomings because it is a sensation that is modified by biological and external influences. For example, the central nervous system actively alters the nerve transmission generated by a noxious stimulus, either by inhibition or excitation at different sites from the spinal cord to the cerebral cortex. In addition, social and cultural influences, beliefs, and biases can influence the sensation and may be linked to negative emotions such as anger, fear, and depression.

The European approach to this global reduction in quality of life in pain patients has been led by the European Federation of IASP Chapters (EFIC). This organization has called for recognition of pain not as merely a symptom but as an important health concern and a disease in its own right. It has sought partnership with groups, such as the International Alliance of Patients' Organisations (IAPO), and industry in order to represent patient interests and to build up a network of resources. These resources range from Web-based information to specialized journals and include education, curriculum development, evidence-based reports, and research tools. One of the best evidence-based reports is that from the Australian and New Zealand College of Anaesthetists and Faculty of Pain Medicine in 2005 on Acute Pain Management and it advocates acute pain management as a basic human right [2].

The response to surgery or trauma is an acute pain sensation that directly follows a noxious event and acts as a warning to seek help. When the pain persists, often the tissues have healed and different physiological systems are activated, leading to complex physical, behavioral, and psychological symptoms. These can result in dependence on medication, overuse and inappropriate use of health care, disability, poor sleep, isolation, and depression. The undertreatment of pain has been well recognized as a public health problem. Hence there have been professional and political pressures to make available and use opioid drugs to manage severe pain. Across the world the frequency of opioid use for pain relief has increased but, interestingly, at one U.S. medical center differences in the amount of prescribed

**TABLE 1 Definitions**

| |
|---|
| **Pain**: Pain is an unpleasant sensory and emotional experience, usually associated with actual or potential tissue damage or described in terms of such damage. The quality and quantity of pain sensations can only be determined from human reports. |
| **Acute pain**: Pain of recent onset and limited duration, usually having an identified temporal and causal relationship to injury or disease, e.g., postoperative pain, pain from sickle cell disease. |
| **Chronic pain**: Pain that persists beyond the point at which healing would be expected to be complete, or that occurring in disease processes in which healing does not take place. Chronic pain may be accompanied by psychological and social disturbance; there may be no evidence of tissue damage. |
| **Nociception**: This describes the physiological components of the neurological pathway used to detect damaging stimuli. It is a process that can be measured in animals and humans. |
| **Neuropathic pain**: Pain initiated or caused by a primary lesion or dysfunction in the nervous system. |
| **Prevalence**: Number of cases in a given population at a designated time. |
| **Incidence**: Number of new cases arising during a defined period of time. |
| **Number needed to treat (NNT)**: The number of people who have to be treated in order for one of them to achieve a specified level of benefit. |
| **Number needed to harm (NNH)**: The number of people who have to be treated in order for one of them to experience an adverse effect. |

opioids to various ethnic groups were measured. In this survey of cancer pain in over 13,000 patients, African Americans were 63% more likely than Caucasian Americans to receive no medications; daily pain was reported in 40% of African Americans but 25% of them received no analgesics [3]. Likewise local pharmacies in minority areas were less likely to have opioids available [4]. This raises issues about barriers to pain management from individual access to treatment to international regulation of analgesic supply and emphasizes the scale of inequalities in the undertreatment of pain.

The economic aspects of pain symptoms have been quantified for chronic pain. In the United States the costs are estimated to be $70 billion for time off work, medications, and health care services. Since quality of life suffers, this has effects on a patient's income, on work performance, on home making, on contribution to the household income, on welfare payments, as well as health care costs. Back pain is the most common site for pain in men, and in the United Kingdom alone this costs the economy £1632 million directly [5]. Of this, 31% is attributable to spending on hospital services, 14% to primary care, and 7% to medication. If indirect costs are included, such as workforce disruption, the total costs may be as high as £10668 million. Maximizing pain relief in this condition is, thus, an important benefit to the whole population when health services are nationally funded.

Procedures in health care facilities have been developed to recognize pain early in order to provide prompt and effective treatment. A clinical approach has been to advance the concept of pain as the fifth vital sign (the others are pulse, blood pressure, temperature, respiration) in order to ensure constant recognition and screening for pain symptoms. This approach has become standardized through a Veterans Health Administration Directive (number 2003-012) and was reviewed in the United States in 2008.

The market for analgesic preparations is thus very large yet diverse because of the multiple biopsychosocial mechanisms for initiating and maintaining the sensation of pain. In the past few years it has been subject to significant influences. One of these involved pharmacovigilance data from the cyclo-oxygenase-2 (COX-2) enzyme inhibitors (COXIBs) that reached a high profile in the media. This led to rofecoxib (Vioxx) being withdrawn in 2003. The COXIBs were developed to improve the gastrointestinal adverse event profile of nonsteroidal anti-inflammatory drugs (NSAIDs) that are prescribed worldwide to more than 80 million people. Then, after the introduction of the drug Celecoxib, clinical trial data for prevention of colonic polyps was reported [6]. The effect of the publication was to generate further substantial media hype in relation to a reported increase in cardiovascular risk. There were calls for drug withdrawal without consideration of both risks and benefits. It effectively left patients with a dramatically limited range of drugs for pain relief. The result was acutely detrimental to both the pharmaceutical industry and patients who required effective pain relief. The long-term effects of this event have been to reevaluate the use of COXIBs and to consider alternative therapies such as the nitro-NSAIDs and other inhibitors of the cycloxygenase enzyme system, for example, COX-3 inhibitors. The use of COX-2 inhibitors has decreased to 30% of the market in the United States and <10% in the UK community. The regulatory response from the European Commission was to initiate a wide ranging review and from the U.S. Food and Drug Administration (FDA) an alert. These have culminated in changes to the safety guidance issued when these type of drugs are prescribed.

Another influence on the UK market has been the effects of tighter regulation on opioid drugs following the Shipman inquiry. Doctors now fear that they can be held criminally responsible for accidental opioid overdose. In a recent poll of general practitioners one in three no longer carry opioid drugs to emergencies in the

community, and there are predications that pain relief in terminally ill patients will suffer. The proposal by England's Chief Medical Officer now out for consultation on doctor's fitness to practice has done nothing to alleviate doctors' apprehensions that have surfaced. Potential pressures on opioid use have also arisen from an increasing population prescribed long-term opioids for noncancer pain. This use of strong opioids has been facilitated first by the marketing of sustained-release oral formulations and transdermal preparations and second by the promotion of national and international (EFIC) guidance. This professionally led approach to therapeutic opioid use in chronic pain conditions is a key to their safe use [7, 8].

## 2 ANALGESIC USE

Population measures of analgesic use are available from different studies. The two population groups can be broadly divided into prescription medications and over-the-counter (OTC) purchases. One approach to quantify the data in Europe and North America has been to conduct surveys to measure painful conditions and associated analgesic use. Analgesics are the most commonly used nonprescription medications, and women report significantly more frequent analgesic use than men even when taking into account social and economic circumstances [9]. For example, 35% of women and 21% of men had used analgesics in the preceding 2 weeks in a Swedish population of 5405 (54% women). The prevalence in men was highest for pain in the back (21%), shoulders (15%), to help sleep (15%), and aching arms and legs (14%). The women had used them for pain in the shoulders (27%), in the back (26%), for sleep (23%), and arm and leg pains (19%). Pain associated with menstruation in the below-52-year-old age group was managed with analgesics in 12%; possibly over a month this figure would double. Although such self-reporting methods may have recall bias and other errors, in most surveys similar findings for the frequency of pain are reported.

The range of OTC includes aspirin, paracetamol (acetaminophen), NSAIDs, for example, ibuprofen, ketoprofen, naproxen, and combinations as well as topical preparations with local anaesthetics for ulcers and hemorrhoids. In recent studies of OTC analgesic use, a mail survey in Scotland determined the prevalence of OTC and prescription analgesic medication use. In the 2 weeks of the survey 37% of respondents had used OTC analgesics and these accounted for 59% of the market [10]. This high level of use was associated with evidence for inappropriate self-management with the potential for drug interactions with prescribed drugs. A similar concomitant use of OTC and prescription analgesics was highlighted in a Finnish survey and was related to daily or continuous pain and a high pain intensity [11]. The potential for increasing the risk of adverse effects has thus been identified and appears to be common to different study populations. In the United States, as part of a national survey, OTC use was prevalent in 74% of the population compared with prescription availability in 9% [12]. Females were more likely than males to use both OTC and prescription analgesics, and with increasing age, prescription use increased whereas OTC use decreased. In a one-month period about 30% of adults used multiple analgesics, and this again demonstrates the potential for adverse effects.

Various self-management strategies for chronic pain relief were investigated in Australia [13]. Analgesic use was defined as a passive strategy and was prevalent in 47%, while exercise was considered an active strategy and was reported by 26% of patients. The study found that use of more active strategies was associated with less disability and a reduction in the use of health care services, so these results were used to advocate community-based treatments for pain management. Overall, 68% of subjects used a combination of active and passive treatments and these patients had the best outcomes.

Analgesic costs in the Unites States have been estimated to be $23 billion for 2004 with a population of 281 million, and double-figure growth is expected in this market in the next decade, partly as a result of more effective drugs being marketed. In England the National Health Service (NHS) has established online reporting of drug costs and estimate their cost as £207 per person for 2004. Hospital pharmacies issue £2309 million of medicines, representing 22% of the total cost of medicines prescribed for 2004. In the community the prescription of analgesic drugs can be charted with some accuracy, and figures for the quantity and net ingredient costs are available online from England for 2005 (http://www.ic.nhs.uk/pubs/prescostanalysis2005). The data for analgesic drugs dispensed is listed alphabetically by chemical entity and the British National Formulary therapeutic class. Figures 1–6 are taken from this data set for opioid and nonopioid analgesics in order to demonstrate the patterns of recent prescription drug use. They amount to about £0.5 billion. Figure 1 shows the number of generic and proprietary formulations of the opioids, NSAIDs, and nonopioid analgesics. Only 4 opioids (pentazocine, codeine, diamorphine, and papaveretum) out of 17 have generic formulations compared with NSAIDs, where all have proprietary brands. Of the NSAID group, there is a large range that can be subdivided into a COX-2 group. Table 2 [14] shows the selectivity of different drugs for the cyclo-oxygenase

**Figure 1** Number of generic and proprietary preparations for (A) opioid drugs, (B) non-steroidal anti-inflammatory drugs (NSAIDs), and (C) other analgesics used in community dispensing in the NHS 2005.

**Figure 2** Costs and quantities of NSAIDs used in community dispensing in the NHS 2005.

enzymes (COX-1 and COX-2). Of the NSAIDs, diclofenac is most commonly used, and this is reflected in the overall cost to the NHS (Fig. 2). In this figure the costs of proprietary formulations of diclofenac are five times higher than generic agents. The situation for tramadol is different (Fig. 3). Although there is one generic preparation, it has 34% of the market and in this formulation is prescribed in lower dose capsules compared to the proprietary brands. For gabapentin (Fig. 3), an antiepileptic drug widely used for neuropathic pain relief, 97% of all costs reflect generic use. It is interesting to speculate why there is this large variation in prescribing habits related to the choice of generic versus proprietary drugs for pain relief.

Figure 4 demonstrates the quantity and cost of opioid use. Fentanyl use in the community is predominantly via the transdermal route, and the cost for this type of formulation makes it the most expensive opioid

**Figure 3** Costs and quantities of other analgesics used in community dispensing in the NHS 2005.

analgesic, second only to the NSAID diclofenac. These benchmark figures provide basic data (excluding hospitals) across a national market. When efficacy is contrasted with the amount and cost of drug prescribed, codeine appears not to be cost effective. Nevertheless when used in combination with paracetamol it achieves a number needed to treat (NNT) of 2.2 (Table 3 [15]), but combined use (i.e., separate prescriptions for codeine and paracetamol) is not visible in the NHS figures unless the cocodamol preparation is prescribed (Fig. 5). The cocodamol formulation is the market leader within the small group of analgesic combinations, both for quantity of use and cost. Interestingly, it is the proprietary rather than the generic formulation that is the most widely prescribed item.

The range of formulations for NSAIDs and selected nonopioids is shown in Figure 6. Those for local application such as gels and mousse/foam are the most costly to prescribe, but the market value of these is small in comparison with overall drug costs. However, paracetamol (acetaminophen) suppositories are of higher cost than other suppositories, and so it has become economical to deliver this drug intravenously in hospitals. The most recently introduced preparation differs from its prodrug propacetamol, which can also be given intravenously after reconstitution. The solubilized preparation has less local effects and can be infused without preparation. In the community over 90% of the paracetamol used is generic.

## 3 ANALGESIC EFFICACY

One of the evidence-based approaches to analgesic use has been to compare the efficacy and side effect profile using a comparative rating based on the number needed to treat (NNT) and the number needed to harm (NNH). The ratings for NNT are calculated on the number of patients reporting at least 50% better pain relief than placebo in randomized, double-blind, single-dose studies in patients with at least moderate pain [15]. This measure of short-term efficacy has been criticized because it does

**Figure 4** Quantity of prescriptions dispensed in the community and the cost of opioid drugs in England in 2005 compared with acute pain relief efficacy as number needed to treat (NNT) [15].

not relate to pain management in clinical practice where drugs are given repeatedly, often in combination. As an alternative evidence-based approach, *Cochrane Reviews* may provide a broader analysis of pain management. For example, in chronic pain where NNTs have not been studied, the use of opioid drugs has been controversial because of their inherent dependency profile. The results of short-term use provide no evidence for opioid efficacy, but for an intermediate period of about 28 days, opioids did reduce neuropathic pain [16]. However, side effects of opioids in this review were common and the calculated NNH are shown in Table 4.

## 4 SELECTION OF ANALGESICS

### 4.1 Pain Measures

Selecting an appropriate analgesic regimen relies on pain measurement and diagnosis. The selection is then

**Figure 5** Number, cost, and quantity of analgesic combinations used in community dispensing in the NHS 2005.

modified according to the patient's response. Nociceptive pain is classically described as originating either in somatic or visceral tissues (or both) mainly because there is a distinct clinical presentation. Somatic pain is described as being well localized, often sharp, whereas visceral pain may present as dull, colicky pain that is poorly localized and often referred to somatic segments and accompanied by autonomic activity such as nausea, sweating, and cardiovascular changes. Interestingly it is somatic pain that has most frequently been researched, and most of the research for NNTs has been related to somatic rather than visceral pain. However, they both present frequently and can be present in the same patient.

Neuropathic pain can be acute or chronic. It is described typically with words such as burning, shooting, and stabbing, indicating the paroxysmal and spontaneous onset of the pain with no clear precipitating features. In addition, there may be altered sensation in skin (e.g., allodynia, where a previously nonpainful stimulus becomes painful) and muscle (e.g., tenderness) or phantom pains when part of the body has been removed (e.g., limb or organ).

Nociceptive and neuropathic pains were thought to respond differently to different analgesics. However, the opioid drugs are effective in both pain types, and it has become acceptable for them to be used in the long term under tightly controlled conditions for pain that is noncancer related. Meanwhile, basic science research is unfolding the mechanisms for specific therapies in relation to receptor sites and nerve membrane activity (Table 5).

Apart from the pain type, the pain intensity is a valuable measure and it depends primarily on patient report. Thus, the influence of sleep, environment, mood, medications, and the like can alter the response to the following questions: How intense is your pain? Is it mild, moderate, or severe? Repeated measures using this standardized verbal questioning can monitor analgesic therapy. Pain can be measured at rest and during exercise, if appropriate, since recovery of function is often an acceptable outcome rather than an overall pain reduction. Verbal scales are simple and fast to use and can be applied to about three-quarters of all patients. Children and patients with special needs require modifications. Some pain measures characterize different elements of the pain sensation and are more applicable to chronic pain where behavioral and emotive responses are important to assess, for example, the McGill Pain Questionnaire.

In clinical trials pain intensity and pain relief are two standard measures taken over time. A change in pain intensity of at least 30% is considered clinically relevant, but most analgesics marketed have achieved 50% in selected patient groups. For patients an important outcome is the overall effect, including improved function, better sleep, and fewer adverse effects. These can be incorporated into a global assessment.

### 4.2 Step-up and Step-down Approach to Pain Management

The World Health Organisation (WHO) and the World Federation of Societies of Anaesthesia have transformed cancer pain relief through a structured therapeutic approach to pain intensity. A three-step approach is advocated that goes up and down the steps depending on pain intensity. For mild pain, the first step, nonopioid

**Figure 6** Relative cost per prescribed item of nonoral formulations of NSAIDs and selected nonopioid drugs in NHS community dispensing 2005.

**TABLE 2 Examples of COX-1 and COX-2 Selectivity [14]**

| NSAID | COX-2:COX-1 Ratio |
|---|---|
| Celocoxib | 7.6:1 |
| Diclofenac | 3.0:1 |
| Etodolac | 2.4:1 |
| Etoricoxib | 106:1 |
| Ibuprofen | 0.2:1 |
| Indometacin | 0.4:1 |
| Meloxicam | 2.0:1 |
| Naproxen | 0.3:1 |
| Piroxicam | 0.08:1 |
| Rofecoxib | 35:1 |
| Valdecoxib | 30:1 |

analgesics are first-line medications. Step 2 involves weak opioids with or without nonopioids, and the third step includes strong opioids again with or without nonopioids. At each step, if needed, adjuvants can also be used and the intermediate step omitted. The outcome for pain management has been found satisfactory in up to 90% of patients. Those 10% of patients whose pain is not adequately managed need other strategies such as anticonvulsants, antidepressants, other adjuvants and alternative routes of drug administration, nerve blocks, or other invasive procedures.

Optimizing results has become important because the ultimate goal is to achieve pain relief quickly and with minimal adverse effects. Thus, the market has increased for anticonvulsant drugs as analgesics for

**TABLE 3 Ranked Order of Number Needed to Treat (NNT) of Different Groups of Analgesics Based on Acute Pain Studies Reported by Bandolier [15]**

| Drug | Number of Patients | NNT |
|---|---|---|
| *NSAIDs* | | |
| Valdecoxib | 473 | 1.6 |
| Ibuprofen | 76 | 1.6 |
| Ketorolac | 69 | 1.8 |
| Rofecoxib | 1900 | 1.9 |

| Vomiting | 8.3 |

**TABLE 5 Analgesic Drugs and Their Sites of Action**

| Functional Site | | |
|---|---|---|
| *Receptors* | *Clinical Drug* | *Comments* |
| NMDA (*N*-methyl-d-aspartate) | Ketamine | Anesthetic—dose related. Dextromethorphan (NMDA antagonist) is in clinical trials for neuropathic pain. Memantine is in clinical trials as a glutamate receptor antagonist. |
| $GABA_A$ | Nitrous oxide | Gaseous (Entonox is 50:50 mixture with oxygen). |
| | Benzodiazepines | Sedation, muscle relaxation. |
| | Ethanol | Social use. |
| | Volatile anaesthetics | Used in low dose, sedative. |
| | Steroids | Also act as disease modifiers; ganaxalone as an anticonvulsant. |
| $GABA_B$ | Baclofen | Antispasmodic. |
| CGRP | None | Endogenous ligand is calcitonin gene-related peptide (CGRP). |
| VIP | None | Endogenous ligand is vasoactive intestinal peptide (VIP). |
| TrkA | None | Nerve growth factor (NGF) antagonists are potential analgesics. |
| Tachykinin | None | Endogenous ligand is substance P. |
| Kinin | None | Endogenous ligand is Bradykinin. BK1 antagonists are potential analgesics. |
| Acetylcholine (nicotinic) | None | Epibatidine, though toxic, is the lead compound. |
| 5HT | None | Endogenous ligand is serotonin (5 hydroxytryptamine). Site of action of antidepressants, e.g., amitriptyline, venlafaxine, duloxetine, milnacipram. |
| Purine (P2X) | None | Endogenous ligand is ATP. |
| Adrenergic $\alpha_2$ | Clonidine, dexmedetomidine | Xen2174, a chi-conopeptide, is a potential analgesic. |
| Opioid | Morphine, fentanyl, diamorphine (heroin), hydromorphone, codeine, sufentanil, oxycodone, oxymorphone, dextropropoxyphene, methadone, pethidine, etorphine, pentazocine,* buprenorphine,* nalbuphine* | *Partial kappa agonists. |
| Cannabinoid | Tetrahydrocannabinol (THC), Nabilone, CBME** | **Plant derived. |
| Vanilloid | Capsaicin | Receptor activated by heat. |
| *Nerve Membrane* | | |
| Sodium channels | Antiarrhythmics, e.g., lidocaine, mexilitene. Anticonvulsants: gabapentin, pregabalin, carbamazepine, phenytoin, valproate, oxcarbazepine, lamotrigine, topiramate, tiagabine | |
| Calcium channels | Ziconotide*** Nifedipine | ***Selective N-type blocker. |
| Denervation | Botulinum toxin | |
| *Peripheral to the Nerve* | | |
| Cyclooxygenase | COX-1 and COX-2 inhibitors | COX-3 inhibition may be the mechanism for paracetamol analgesia. |
| Nitric Oxide (NO) | NO-based drugs | NO- NSAIDs, NO-paracetamol are in preclinical tests. |
| *Cell Nucleus* | | |
| Gene therapies | None | Some inherited painful neuropathies may respond; activation of glia in neuropathic pain states. |
| *Synapse* | | |
| Synaptic vehicle exocytosis | Levetiracetam | Anticonvulsant limited clinical data in neuropathic pain. |

chronic pain conditions because of their sodium channel blocking effects on nerve membranes. In the United Kingdom about 20% of analgesic costs in the community are for gabapentin and pregabalin.

Some evidence now suggests that early application of invasive procedures in cancer pain may result in better pain relief and less side effects [17]. Thus, there are recommendations to find evidence for invasive procedures being an effective part of each step and not used as a last resort. It is in this context that a new intrathecal peptide analgesic, ziconotide, has entered the market. It is the first and only neuronal-type calcium channel blocker. At present there have been no comparative studies with other intrathecal analgesics. All invasive procedures carry a risk of infection, in this case meningitis, but the adverse effects specific to ziconotide include depression, cognitive impairment, and hallucinations. These relatively severe psychiatric risks preclude use of this drug for routine pain relief. It is, therefore, appropriate to consider the record of intrathecal drugs such as local anaesthetics and opioids (e.g., fentanyl, sufentanil) that are routinely used for relief of severe pain. Pharmacovigilance data for severe adverse effects to them is comparatively rare [18]. Furthermore, specific opioid antagonists for peripheral activity such as methylnaltrexone or alvimopan can reduce gastrointestinal dysfunction associated with acute opioid use.

The therapeutic opportunities for the WHO steps are shown in Table 6 for different painful conditions. Cancer pain affects about 1% of the U.S. population and requires a large range of analgesic agents. Opioids are the standard medication, but breakthrough pain is an important issue, so some drug formulations have been successfully developed to overcome this (e.g., Actiq). Postoperative pain is common with over 50 million procedures in the United States annually, yet many patients complain of inadequate relief or unwanted adverse effects. Opioids and NSAIDs are the standard analgesics used after surgery, and the use of more than one analgesic therapeutic group is essential in order to minimize pain. Postoperative pain varies with the type and site of surgery and is usually managed by intraoperative analgesia and local anaesthetic nerve blocks followed by regular parenteral and oral medications. The majority of pain management is on the WHO step-down basis from parenteral to oral medications. Neuropathic pain is associated with diseases that are increasing in frequency such as diabetes and human immunodeficiency virus (HIV) infection. This type of pain is not life-threatening and often continues throughout a lifetime, so this is an important market given the present lack of drug specificity and the high costs of drugs licensed for use in neuropathic pain. New agents being considered for long-term neuropathic pain management include those that prevent neural degeneration such as prosaptides [19].

The step-up and step-down approach to pain management identifies the opportunities for combined therapies, but only of analgesic drugs. Table 7 [20] lists the multiple strategies that can be used simultaneously to achieve adequate pain relief; they include pharmacological, physical, and psychobehavioral approaches. For analgesic drugs, the advantages of using more than one drug are that more than one neural site for pain transmission can be targeted, drug dosage can often be reduced and hence side effects, and if the formulation is in one preparation then costs of prescribing and distribution will be reduced—providing efficiency to patients and prescribers.

### 4.3 The At-Risk Patient

Over many years drug development has precluded at-risk groups of patients such as pregnant women and the young from clinical trials. This approach has led to many drugs being used off licence in these populations. In the next few years this situation should change with the introduction in the European Union of postmarketing pharmacovigilance. Another at-risk group includes the elderly because of the decline in normal renal and hepatic function. Pain is frequent in the elderly, and this group of patients is expected to increase in future because of longer life expectation.

Another approach to defining who is at risk is to consider new developments in personalized medicine. Women are overall more likely to suffer adverse drug effects than men, and this finding is not wholly related to physical differences. These effects can determine the pattern of prescription and OTC drug use and behavior toward analgesics. Hence, any method to improve compliance or drug selection would be welcomed by patients, prescribers, and pharmaceutical companies. Thus, the concept of designer analgesics is now advancing through stages such as pharmacogenetics where genetic factors such as the CYP450 (cytochrome P450) liver enzymes are identified, pharmacogenomics where the sites of action of drugs/diseases are characterized, and phenotyping where the metabolic profile of drugs can be determined, for example, the conversion of codeine to morphine.

Others at risk are those who are dependent on opioids. One approach has been the design of a new formulation of oxycodone, Remoxy, that is sticky, which prevents it being crushed or snorted. A market of over $1 million is forecast for this unique abuse-resistant product.

**TABLE 6 Choice of Standard Agents for Selected Painful Conditions**[a]

| | 2, 3 | 1, 2 | 1, 2 | 1, 2 | 1, 2, 3 | 1, 2, 3 | 1, 2, 3 | 1, 2, 3 |

| Rectal | |

## 5 DRUG DEVELOPMENT

The mechanistic approach to development of analgesics has been well researched, but there are few compounds in clinical use compared with those available to laboratory workers for antinociceptive studies. However, in recent years innovative approaches to pain relief have included evidence-based professional guidelines [2], combining therapeutic strategies, improvements in drug formulations, and identification of patient and prescriber behaviors that limit effective drug use.

The opportunity to use old drugs in new formulations has made a welcome improvement in delivering drugs to patients, especially the opioids (Table 8). They have increased time between doses, removed messy delivery systems, and added secure and safer dosing regimes.

A structured approach to the analgesic market has been to identify the frequency and type of pain, how it is managed (e.g., mechanism-based and evidence-based approaches), and what combinations of therapies are used, what the unfulfilled needs are for OTC and prescribers, and how to improve therapeutic strategies to achieve maximum benefit for patients.

# ANTIVIRAL MARKET OVERVIEW

Anita Arora, Natalia Mendoza, and Stephen K. Tyring
*Center for Clinical Studies, Houston, Texas*

## 1 INTRODUCTION

According to the latest figures published today in the UNAIDS/WHO 2006 AIDS Epidemic Update, an estimated 39.5 million people are living with the human immunodeficiency virus and 170 million people are thought to be infected with hepatitis C virus [1]. These figures just illustrate that the number of viral infections are rising and more and better antivirals are urgently required. Approximately 40 antiviral drugs have been officially approved for clinical use [1], and at least half of them are used in the treatment of human immunodeficiency virus (HIV) infections (acquired immuno deficiency syndrome; AIDS). The other antivirals that are readily available include those for the treatment of herpes simplex virus (HSV), varicella-zoster virus (VZV), cytomegalovirus (CMV), influenza virus, respiratory syncytial virus (RSV), and hepatitis B (HBV) and C virus (HCV) infections [2].

There are several other important virus infections for which no antiviral drugs have been developed; even for those infections for which antiviral drug therapy exists, there is still substantial room for advancement in terms of higher potency and/or increased selectivity or safety. The approaches toward the treatment of HIV, HBV, and HCV, herpesvirus, human papillomavirus (HPV), and poxvirus infections will be reviewed in this context.

## 2 ANTIVIRAL DRUGS FOR HUMAN IMMUNODEFICIENCY VIRUS INFECTIONS

Currently, there are over 20 antiretroviral drugs approved by the Food and Drug Administration (FDA) falling into 5 categories: nucleoside analogs (zidovudine, lamivudine, didanosine, zalcitabine, stavudine, abacavir, emtricitabine), nucleotide analogs (tenofovir), nonnucleoside analogs (nevirapine, delavirdine, efavirenz), protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, fosamprenavir, atazanivir, lopinavir, tipranavir, darunavir), and fusion inhibitors (enfuvirtide). Five combination antiretrovirals exist to increase medication compliance: Combivir (zidovudine/lamivudine), Trizivir (zidovudine, lamivudine, abacavir), Truvada (tenofovir/emtricitabine), Epzicom (lamivudine/abacavir), and the latest approved (July 2006) Atripla (efavirenz, emtricitabine, tenofovir). Highlights of each class of drug will be described before development of new therapeutics agents is discussed further. The goals of using antiretroviral drugs are to reduce viral load for a prolonged period and delay disease progression. General guidelines for treatment initiation of antiretroviral therapy are reviewed in Table 1 and dosages are listed in Table 2.

### 2.1 Nucleoside Analogs

Nucleoside reverse transcriptase inhibitors (NRTIs) were the first family of antiretrovirals to be created against HIV. Zidovudine was the first FDA-approved (1987) drug for HIV infection. NRTIs are activated following intracellular phosphorylation. The triphosphorylated metabolites attach to viral reverse transcriptase and are integrated into the growing deoxyribonucleic and acid (DNA) chain where they bring about DNA termination. The end result is that they inhibit ribonucleic acid (RNA)-dependent DNA synthesis [3].

**TABLE 1 Overview of Guidelines for Initiation of Antiretroviral Therapy in Adults**

| |
|---|
| AIDS disease |
| Symptomatic infection |
| CD4 count < 200/mm$^3$ |
| Plasma HIV RNA levels of >55,000 copies/mL (RT-PCR) |
| Plasma HIV RNA levels of >30,000 copies/mL (RT-PCR) |
| Consider treatment in patients with CD4 count 200–350/mm$^3$ |

Resistance to one NRTI can often lead to resistance to all of the others.

### 2.2 Nucleotide Analogs

Tenofovir is a nucleotide analog that is used in combination therapy (Truvada, tenofovir/emtricitabine). Its mechanism of action is similar to nucleoside analogs, causing chain termination by competitive inhibition. Trials have demonstrated that the use of tenofovir in highly active antiretroviral therapy (HAART) is successful at suppressing RNA titers of resistant strains. Fortunately, cross resistance with nucleoside analogs has not yet been described [4–6].

### 2.3 Nonnucleoside Analogs

Nonnucleoside reverse transcriptase inhibitors (NNRTI) affect replication at the reverse transcriptase (RT) stage, like nucleoside analogs. However, they utilize a different mechanism of action by binding noncompetitively to the viral RNA-dependent DNA polymerase, altering its structure, and thus inhibiting its function. NNRTIs are active in their native state and do not require phosphorylation. As with other antiretrovirals, monotherapy is linked with the emergence of resistance and cross resistance exists among NNRTIs. Nonnucleoside analogs are approved for use in combination therapy against HIV-1 infections and are not active against HIV-2 infections [7, 8].

### 2.4 Protease Inhibitors

Protease inhibitors (PI) became widely available in 1996, and their mechanism of action blocks the protease enzyme involved in the final processing of viral proteins, subsequently resulting in decreased assembly of new progeny viruses from newly infected or chronically infected cells. This is a distinct advantage over RT inhibitors, which only inhibit replication in newly infected cells. PIs are currently used in combination with NRTI or NNRTI. This combination results in a 2-log decrease in viral load in the majority of HIV-infected individuals

**TABLE 2 Adult Dosages of FDA-Approved Antiretroviral Agents**

| Generic Name | Common Abbreviations | Adult Dosages[a] |
|---|---|---|
| *Nucleoside Reverse Transcriptase Inhibitors* | | |
| Zidovudine | AZT, ZDV | 300 mg b.i.d., 200 mg t.i.d. |
| Didanosine | ddI | 200 mg b.i.d., 400 mg q.d. |
| Zalcitabine | ddC | 0.75 mg t.i.d. |
| Stavudine | d4T | 20–40 mg b.i.d. |
| Lamivudine | 3TC | 150 mg b.i.d., 300 mg q.d. |
| Abacavir | ABC | 300 mg b.i.d. |
| Emtricitabine | FTC | 200 mg q.d. |
| Zidovudine + Lamivudine | AZT + 3TC | one b.i.d. |
| Zidovudine + Lamuvidine+ abacavir | AZT + 3TC + ABC | one b.i.d. |
| Lamivudine + Abacavir | 3TC + ABC | one q.d. |
| Tenofovir + Emtricitabine | TFV + FTC | one q.d. |
| Efavirenz + emtricitabine+ tenofovir[b] | EFV + FTC + TFV | one q.d. |
| *Nucleotide Reverse Transcriptase Inhibitor* | | |
| Tenofovir | TFV, TDF, PMPA | 300 mg q.d. |
| *Nonnucleoside Reverse Transcriptase Inhibitors* | | |
| Nevirapine | NVP | 200 mg b.i.d. |
| Delavirdine | DLV | 400 mg t.i.d. |
| Efavirenz | EFV | 600 mg q.d. |
| *Protease Inhibitors (PIs)* | | |
| Saquinavir | SQV | 400 or 1000 mg b.i.d. |
| Indinavir | IDV | 800 mg q8h |
| Ritonavir | RTV | 600 mg b.i.d. |
| Nelfinavir | NFV | 1250 or 750 mg t.i.d. |
| Amprenavir | APV | 1200 mg b.i.d. |
| Fosamprenavir | f-APV | 1400 mg b.i.d. |
| Atazanavir | ATV | 400 mg q.d. |
| Lopinavir + Ritonavir | LPV/r | Three b.i.d. |
| *Fusion Inhibitors (FIs)* | | |
| Enfuvirtide | T-20 | 90 mg s.c. b.i.d. |

[a]Frequently used dosages: b.i.d. = twice daily, t.i.d. = three times a day; q.d. = every day; q8h = every 8 hours; s.c. = subcutaneously.
[b]Nucleotide reverse transcriptase inhibitor.

while RT inhibitors used in monotherapy only produce a 0.5-log decrease [9].

### 2.5 Fusion Inhibitors

Fusion inhibitors, a new novel class of antiretroviral drugs, bind to proteins on the viral envelope and inhibit the conformational change required for fusion between the viral envelope and CD4 cells. Currently, the only drug in its class, enfuvirtide, has not demonstrated cross resistance with other antiviral medications. It is administered by abdominal subcutaneous injections twice daily.

### 2.6 Therapeutic Investigational Drugs

Although antiretroviral medications are fairly new in the armamentarium of medications against HIV infection, resistance to antiretrovirals can already be encountered in treatment-naïve patients [10]. HIV has generated more efforts toward antiviral drug development than any other virus. As more is identified in the cycle of viral replication, new targets for treatments are being studied. Each step in the entry of HIV into cells is now being targeted for therapeutic design (Table 3). Furthermore, new nucleoside analogs, NNRTIs, and PIs with increased activity against resistant strains are being studied for their use in combination therapy [11, 12].

**TABLE 3 Emerging Drug Targets for Antiretroviral Therapy**

| |
|---|
| Entry Inhibitors |
| • *Attachment* |
| Cyanovirin-N |
| Cyclotriazadisulfonamide analogs |
| PRO 2000 |
| TNX 355 |
| PRO 542 |
| BMS 806 |
| Peptide T |
| • *Co-receptor binding* |
| SCH-D (CCR5 antagonist) |
| Maraviroc (CCR5 antagonist) |
| Aplaviroc (CCR5 antagonist) |
| PRO 140 (CCR5 antagonist) |
| AMD 070 (CXCR4 antagonist) |
| • *Fusion* |
| Enfuvirtide (using needle-free injection device) |
| Tifuvirtide |
| Integrase Inhibitors |
| L870810 |
| JTK-303 |
| Maturation Inhibitors |
| PA 457 |

***New Targets: Entry*** The steps of viral entry present three unique targets for inhibition: (1) attachment of virions to the cell surface via nonspecific interactions and CD4 binding, (2) co-receptor binding, and (3) fusion. The envelope protein (Env) on the surface of virions regulates HIV's entry into target cells [13, 14]. Env is composed of an outer protein, glycoprotein (gp) 120, and a transmembrane protein, gp 41, which are brought together on the surface of the virion. Env interactions with cell surface molecules allow virions to attach to target cells, and then permit entry subsequent to specific, sequential interactions with its cell surface receptor CD4 and co-receptor CCR5 or CXCR4 [15, 16]. In addition, some entry inhibitors are being investigated as potential microbicides to prevent mucosal transmission of HIV [17, 18].

*Attachment Inhibitors* HIV attachment inhibitors include agents that interact with the virus or the target cell to inhibit virion absorption/attachment or Env–receptor interactions. Attachment inhibitors can be further categorized into those with nonspecific or specific modes of action. Nonspecific inhibitors of HIV adsorption/attachment to the cell surface include soluble polyanions, such as dextran sulfate and heparin, that aim at basic regions of gp120 to inhibit cell surface binding and co-receptor interactions [19, 20]. Specific inhibitors (targeting CD4) include agents that down-modulate CD4, ligands to CD4 (both of which have potential outcomes on immune function), and agents that bind to Env to prevent Env–CD4 binding or functional interactions. Several compounds are currently progressing through clinical trials [21].

*Co-receptor Binding* Inhibitors of co-receptor interactions characterize a second group of entry inhibitors that include proteins, small molecules, and antibodies. These co-receptor-binding inhibitors interact either with CCR5, CXCR4, or Env to preclude functional Env–co-receptor interactions. CCR5 using viruses (R5 tropic) are involved in HIV transmission. Subsequently in infection, approximately 20–50% of individuals acquire viruses that can use CXCR4 as well as CCR5 (dual tropic R5/X4). A small percentage of the population acquires viruses that use CXCR4 but not CCR5 (X4 tropic) [22, 23]. The chemokine macrophage inflammatory protein (MIP)-1α/CCL3, MIP-1β/CCL4, and RANTES/CCL5 bind to CCR5, and stromal cell-derived factor-1-α (SDF-1) binds CXCR4 to prevent viral infection, respectively [24–26]. Chemically adapted chemokine derivatives, which have been produced with more

effective HIV inhibitory activity, are currently being investigated in clinical trials.

*Fusion Inhibitors* Fusion inhibitors represent the first group of entry inhibitors for which there is an approved drug. Enfuvirtide, a 36-amino-acid peptide, was FDA approved in 2003 for use together with other antiretrovirals in treatment-experienced individuals with evidence of HIV-1 replication despite antiretroviral usage. Enfuvirtide targets a fusion intermediate conformation of Env [27–29] and has further been reported to interact with gp120 to inhibit CXCR4 binding [30]. Administration of enfuvirtide using a needle-free injection device is currently in development [31]. Other peptide-based and small-molecule inhibitors of fusion that aim at gp41 [32] are currently in clinical development. Small-molecule inhibitors hold the most potential for widespread use due to their decreased production costs and oral availability.

***Integrase Inhibitors*** Merging of the viral genome and host chromosomal DNA (cDNA) is the trademark of retroviral infection. This step of retroviral infection is performed by the integrase enzyme and is labeled integration. Like reverse transcriptase, integrase is a promising therapeutic target due to its distinctive enzymatic activity. However, unlike reverse transcriptase, this target continues to be clinically unused despite extensive drug development [33, 34]. Two distinctive targets exist for disrupting integration: (1) inhibiting the action of the integrase enzyme directly through conventional small-molecule inhibitors; or (2) designing agents that inhibit the formation of the preintegration complex (PIC), which occurs immediately after the uncoating of the viral capsid. Blocking the PIC may inhibit nuclear entry and/or significantly decrease the activity of integrase. Clinical trials are underway with small-molecule inhibitors through Merck Research Laboratories and Gilead Sciences [21]. Alongside reverse transcriptase, protease and entry inhibitors, integrase inhibitors denote the next class of antiretroviral agents most likely to be used for the treatment of HIV-1 infection.

***Inhibitors of Maturation*** Protease inhibitors are the essential component of HAART, and they prevent the necessary proteolytic processing of the gag and gag-pol polyproteins. The proteolytic processing allows the structural maturation of the virus particle and the activation of the viral enzymes along with viral budding. Resistance to protease inhibitors (PIs) occurs because of continued viral replication while the drug is present. PA 457 is an alternative drug that inhibits viral maturation at the substrate of the protease, unlike conventional PIs that act at the enzyme's active site. This alternative drug that targets viral maturation has retained its potency against isolates resistant to approved reverse transcriptase and PIs [35], and has been granted fast-track review status by the U.S. FDA while it is currently in phase II clinical trials.

## 3 ANTIVIRALS FOR HEPATITIS B AND C INFECTIONS

Individuals that are chronically infected with hepatitis B (HBV) and C (HCV) are at risk of developing cirrhosis and, subsequently, hepatocellular carcinoma. Antiviral therapy offers the only course of interrupting this progression. Until now, recombinant interferon α (IFN-α) and the nucleoside/nucleotide analogs lamivudine, adefovir dipivoxil, entecavir, and telbuvidine are the sole licensed drugs for the treatment of chronic hepatitis B. For hepatitis C, recombinant or PEGylated interferons (PEGIFN) in combination with ribavirin are used for chronic hepatitis C virus infections. Improvements in current therapies are needed for both hepatitis B and C due to viral resistance, effectiveness, significant cost, and adverse effects [36, 37].

### 3.1 Antivirals for Hepatitis B

Patients with chronic HBV infection who can benefit from therapeutic intervention are listed in Table 4 along with current practical recommendations. In surveillance of viral hepatitis serology in individuals with elevated alanine aminotransferase (ALT) or in screening for HBV in those that have risk factors, the finding of hepatitis B surface antigen (HBsAg) results in the diagnosis. This subsequently leads to the testing for hepatitis B e antigen (HBeAg), hepatitis B e antibody, and HBV DNA. Detection of hepatitis B surface antibody indicates immunity via vaccination or past infection. The goals of treatment of chronic hepatitis B infection are the initiation and maintenance of HBV suppression resulting in improved clinical outcome [38]. Loss of HBsAg along with or without seroconversion is the gold standard for resolving the HBV infection. Two potential mechanisms exist for the treatment of chronic HBV, an immune modulating approach and a completely antiviral approach.

***Interferons*** Interferons have immunomodulatory, antiproliferative, and antiviral effects; and furthermore they have been in use for years in the treatment of chronic HBV infection. The two IFN subgroup entities that have been most frequently used are IFN-α 2a and IFN-α 2b, and both are now present in the PEGylated form by conjugation to bis-monomethoxy polyethylene glycol (PEG-IFN). PEG IFN's efficacy

**TABLE 4 Practical Recommendations for Therapeutic Intervention of Chronic Hepatitis B**

| Clinical Findings | Therapeutic Intervention |
|---|---|
| HBsAg carrier | Observation[a] |
| Hbe Ag-positive or -negative (hepatitis B low HBV DNA ($\leq 10^4$ IU/mL) | PEG IFN[b] or adefovir[c] or entecavir[d] or lamivudine[e] or telbivudine[f] |
| Normal ALT | |
| HBe Ag positive | |
| Moderate to high HBV DNA ($\geq 10^5$ IU/mL) | Lamivudine or adefovir or entecavir or telbivudine or PEG IFN |
| Abnormal ALT (≥2× normal level) | |
| HBeAg negative | |
| Moderate to high HBV DNA ($\geq 10^4$ IU/mL) | Lamivudine or adefovir or entecavir or telbivudine |
| Abnormal ALT (≥2× normal level) | |
| HbeAg positive or negative | |
| HBeAg positive or negative | Lamivudine or adefovir or Entecavir or telbivudine |
| Cirrhosis, decompensated | |

[a]If immunosuppression planned, then recommended treatment is lamivudine.
[b]Five million units per day for a minimum of 16 months, given intramuscularly or subcutaneously [39].
[c]10 mg per day for 48 weeks [39].
[d]0.5 mg per day for 52 weeks (lamivudine-resistant patients are given a 1.0-mg daily dose for the same course) [40].
[e]Available in tablet or oral solution, and tablet form is 100 mg/day.
[f]600 mg of telbivudine daily for 52 weeks [41].

against HBV is currently under assessment, although it is already licensed for the treatment of chronic HCV infection [36].

***Lamivudine*** Lamivudine, a deoxycytidine analog, is an antiretroviral nucleoside reverse transcriptase inhibitor that results in premature chain termination subsequent to incorporating into newly synthesized HBV DNA. It is used in patients with positive and negative HBeAg chronic hepatitis and in place of IFN in those with decompensated cirrhosis and active liver inflammation. Drug-resistant viruses have been observed with extended treatment.

***Adefovir Dipivoxil*** Adefovir dipivoxil, an adenine nucleotide analog, is an antiretroviral nucleotide reverse transcriptase inhibitor that is used for the treatment of both HBeAg–positive and -negative individuals, including those individuals that are lamivudine resistant. The goal of therapy with adefovir is to slow the progression of HBV and improve liver inflammation and fibrosis [39].

***Entecavir*** Entecavir (ETV), a novel deoxyguanosine analog, differs from the other nucleoside/tide reverse transcriptase inhibitors in that it is >100-fold more potent against HBV in culture and displays no significant activity against HIV. Additionally, while lamivudine and adefovir are obligate DNA chain terminators, ETV halts HBV DNA elongation after incorporating a few additional bases. It is indicated for use in people infected with lamivudine-resistant HBV as well as patients suffering from persistently elevated levels of ALT/AST (asparte aminotransferase) [40].

***Telbivudine*** Telbivudine, the newest drug to enter the market against chronic HBV, is most unique in its mechanism of action in that it targets the DNA replication of the virus. It inhibits the HBV DNA polymerase's reverse transcriptase and results in subsequent inhibition of viral replication, improvement of liver inflammation, and suppression of the viral infection [41].

***Combination Therapy*** Due to restricted efficacy and drug resistance, combination therapy with two or more nucleos(t)ide analogs, or with IFN-α, is an alternative choice that might demonstrate higher sustained response rates.

***Therapeutic Investigational Drugs*** Several nucleos(t)ide analogs are currently in phase II/III clinical trials for the treatment of HBV. Among them are tenofovir, emtricitabine, and clevudine. The use of any of these analogs in combination therapy remains to be established [42, 43].

### 3.2 Antivirals against Hepatitis C

In the acute phase of infection with HCV, the virus escapes detection by the immune system in the vast number of the cases and subsequently leads to persistent infection in between 50 and 90% of cases [44]. Treatment is typically considered during the chronic phase of infection, which is defined as the presence of HCV RNA in the peripheral blood (detected by polymerase chain reaction, PCR) during a minimum 6-month period. The presence of elevated ALT also signifies chronic disease; however, 20–50% of patients have persistently normal aminotransferase levels and should not be excluded from therapy. The main goal of antiviral therapy is to prevent progression of liver fibrosis to cirrhosis, end-stage liver disease, and hepatocellular carcinoma (HCC).

***Interferons*** IFN-α has been the mainstay of antiviral therapy in HCV infection, and it inhibits viral replication indirectly through activation of natural killer (NK) cells and cytotoxic T cells and by way of altered cytokine synthesis [45]. IFN also directly inhibits viral RNA and

protein synthesis. In 2002, the FDA approved the use of PEG-IFNs as monotherapy for HCV patients that have not had prior treatment with IFN. Combining PEG to the IFN molecule has made significant advancement in antiviral therapy against chronic HCV. It has allowed an increase in absorption time and half-life and has decreased the clearance of the drug [46]. As a consequence of these events, a longer duration of action on the patient can occur while preventing viral replication between doses.

***Ribavirin*** Ribavirin, a nucleoside analog, is ineffective at reducing viral load as a monotherapy but has improved effectiveness when used in combination with IFN-α [47, 48]. The exact mechanism of action is unclear, but it is known that it enhances T-cell-mediated immunity against viral infection, suppresses viral RNA replication, directly inhibits HCV-encoded RNA-dependant RNA polymerase, and reduces the production of genomic viral RNA by way of increasing the mutation rate of RNA viruses [49].

***Combination Therapy of IFN and Ribavirin*** The HCV treatment has developed from the use of IFN alone to the combination of IFN plus ribavirin since IFN monotherapy has not yielded satisfactory results. PEG-IFN-α monotherapy is more effective than IFN-α monotherapy but less than the combination of IFN-α and ribavirin [50–54]. The current treatment of PEG-IFN in adjunct with ribavirin is now the best therapy for the treatment of chronic HCV [55]. This therapy is dependant upon the HCV genotype. Usually, genotype 1 requires 12 months of therapy with PEG-IFN once a week subcutaneously in combination with 1000 mg ribavirin. In patients with genotypes 2 and 3, 6 months of therapy with PEG-IFN and 800 mg ribavirin is adequate. Despite improvements in current therapy, less satisfactory results have been attained in particular patient populations (e.g., African-American ethnicity, older age, and possibly obesity) [56]. Furthermore, viral response to antiviral therapy fluctuates between genotypes, and ribavirin is associated with the frequent side effect of hemolytic anemia that subsequently limits dosing. In addition, the number of nonresponders to current therapy will continue to rise as more patients with chronic HCV are treated. The rising number of nonresponders emphasizes the necessity for the development of more efficacious antivirals against HCV.

***Therapeutic Investigational Drugs*** Emerging therapeutic agents are currently under clinical investigation (Table 5) include novel IFNs and IFN delivery systems, ribavirin analogs, antisense oligonucleotides, short interfering RNAs (siRNAs) and ribozymes, enzyme inhibitors, immunomodulatory agents, antifibrotic agents, therapeutic vaccine, and antibodies.

## 4 ANTIVIRALS FOR HUMAN HERPESVIRUS INFECTIONS

Human herpesviruses (HHV) include eight types of viruses that can produce a variety of illnesses. Among the HHV family are the herpes simplex virus type 1 and type 2 (HSV-1 and HSV-2), which the majority of the time result in herpes labialis (fever blisters/cold sores) and genital herpes, respectively. Both herpes labialis and genital herpes can be caused by either virus. Other disease entities caused by HSV-1 and HSV-2 include gingivostomatitis, ocular disease, herpes gladiatorum, eczema herpeticum, herpetic whitlow, neonatal herpes, lumbosacral herpes, herpetic keratoconjunctivitis, herpes encephalitits, cervicitis, and erythema multiforme [57]. HHV type 3 (varicella zoster virus, VZV) results in chickenpox in its primary form and herpes zoster or shingles in its recurrent form. The rest of the types of the HHV family and ensuing conditions are listed in Table 6. The three main antiviral agents that are effective against HSV-1, HSV-2, and VZV are acyclovir, valacyclovir, and famciclovir. The dosages of these antiviral agents against HSV-1, -2 and VZV, for both immunocompetent and immunocompromised patients, are listed in Table 7.

***Acyclovir*** Acyclovir (ACV), a guanosine analog, is the most familiar and widely used antiviral in the world [58]. ACV, once phosphorylated by herpes-specific thymidine kinase (TK), inhibits viral DNA polymerase by serving as an obligate chain terminator [59]. Indications for the use of ACV are found in Table 8. ACV can be given topically, orally, and intravenously. The oral form of administration is the most widely used for HSV infections. Intravenous ACV is utilized for severe illness and in the immunocompromised. Indications consist of disseminated HSV disease, complicated primary infection, neonatal infection, eczema herpeticum, herpes encephalitis, and HSV that is not treated successfully with oral therapy. Intravenous ACV is administered to individuals that are immunocompromised due its greater bioavailability and has been the mainstay of therapy in this patient population afflicted with primary or recurrent VZV infection [60].

***Valacyclovir*** Valacyclovir (VACV) is an oral prodrug of acyclovir and has an oral bioavailability three to five times greater than that of oral ACV, which is its main difference from ACV. When VACV is administered

**TABLE 5 Antiviral Agents for HCV in Current Clinical Investigation**

| Category | Name | Notes |
|---|---|---|
| Interferon | Omega Interferon | Genetically engineered IFN, oral prodrug formulation in development |
| | Multiferon | Natural IFN |
| | Albuferon | IFN fused to albumin molecules |
| | ANA 245 | Nucleoside analog that induces multiple cytokines, including IFN-α |
| | Resiquimod | Induced number of cytokines including IFN-α |
| Ribavirin analogs | Levovirin | L-isomer of ribavirin (linked with lesser degree of hemolytic anemia) |
| | Viramidine | Prodrug that is immediately converted into ribavirin in vivo |
| Antisense oligonucleotides | ISIS-14803 | Genetically inhibits production of disease-causing proteins |
| Ribozymes | Heptazyme | Cleaves RNA interrupting life cycle of virus[a] |
| Enzyme inhibitors | BILN 2061 | Serine protease inhibitor[a] |
| | VX-950 | Protease inhibitor |
| | NM-283 | RpRd polymerase inhibitor (oral nucleoside analog) |
| | JTK 003 | RpRd polymerase inhibitor, a nonnucleoside |
| | Merimebodib (VX-497) | IMPDH inhibitor[b] |
| | Mycophenolate mofetil | IMPDH inhibitor[b] |
| Immunomodulatory agents | Histamine dihydrochloride | Exhibits immunomodulatory effects |
| | Thymosin alfa-I | Stimulates immune system |
| | Amantadine | Current antiflu therapy |
| Antifibrotic agents | Interferon-γ | Result in reversal of liver fibrosis (by histological scoring system) |
| | Interleukin-10 | Reduces fibrosis |

(orally), it is practically as potent as intravenous ACV [57]. Indications for its use are found in Table 9.

***Famciclovir*** Famciclovir (FCV) is the oral prodrug of penciclovir (PCV), an acyclic nucleoside. Similar to ACV, it is necessary for PCV to be phosphorylated for it to be active. Phosphorylated PCV has a much longer intracellular half-life (10–20 h in HSV-infected cells and 7 h in VZV-infected cells) than phosphorylated ACV (less than 1 h in HSV- and VZV-infected cells) [59]. Oral FCV has a 77% bioavailability in comparison to 15–30% biovailability of oral ACV and 55% for oral VACV [61, 62]. FCV is an effective oral agent that can be used as an alternative to intravenous antiviral therapy in immunocompromised individuals afflicted with herpes zoster. However, it is necessary to monitor patients very closely and administer intravenous ACV if any signs or symptoms of disseminated disease occur [63]. Indications for the use of FCV are listed in Table 10.

***Therapeutic Guidelines*** Overall, ACV, VACV, and FCV are equivalent in safety and efficacy. In deciding therapy against HSV infection, VACV and FCV provide the convenience of lower dosing frequency, and thus enhancing patient compliance; however, VACV and FCV are more costly than ACV. In the therapy of VZV, VACV and FCV are, to some extent, more effective in lowering the duration of zoster-associated pain than ACV due their superior bioavailability [64, 65].

Resistance to ACV can arise from uncontrolled replication of HSV, particularly in immunocompromised patients. ACV-resistant HSV is often cross resistant to VACV and FCV as well. Resistance to ACV regularly

results from mutations in the viral thymidine kinase gene and less often with mutations in viral DNA polymerase [66, 67]. Patients that are not successfully treated with standard therapy with oral and intravenous acyclovir can be treated with foscarnet or cidofovir. Foscarnet and cidofovir are more toxic than ACV and thus are not administered as first-line therapy for HSV infections. Cidofovir can be compounded for topical use and neither drug requires phosphorylation by thymidine kinase to inhibit viral DNA polymerase.

***Therapeutic Investigational Drugs*** Emerging therapies against HHV infections include the newly discovered bicyclic furo(2,3-d) pyrimidine nucleoside analogs (BCNAs). BCNAs are extremely selective in their anti-VZV activity; more specifically, they only inhibit VZV replication and not the replication of any other viruses such as HSV [68, 69]. Resiquimod, an investigational immune response modifier and Toll-like receptor (TLR) 7 and 8 agonist, has been shown to reduce the frequency of HSV-2 mucosal reactivation [70, 71]. Novel anti-HSV agents that target the viral helicase-primase complex, such as thiazolylphenyl derivatives BILS 179BS and, particularly, BAY 57-1293 have been reported to have in vivo efficacy in animal models of HSV-1 and HSV-2 infections [72, 73]. The helicase-primase complex is composed of three viral proteins: HSV UL5, UL-8, and UL52 gene products. All three unwind the double-stranded viral DNA and produce the primer/templates for DNA synthesis by the viral DNA polymerase. It has been stated that BAY-1293, in its function as helicase-primase inhibitor, is superior to all other antiviral agents currently used for HSV infections [74]. This supports the continued pursuit of helicase-primase inhibitors against HSV. An extension of this approach involves compounds that interact with the formation of the HSV DNA polymerase complex (e.g., BP5) [75]. Targeting protein-to-protein interactions comprise a novel target for the generation of antiviral agents for continuing exploration as antiviral therapy.

## 5 ANTIVIRALS FOR HUMAN PAPILLOMAVIRUS (HPV)

HPV-associated diseases in humans have had an augmented significance over the years and are currently a foremost concern for public health. The majority of HPVs that cause significant diseases in humans are grouped into the genus α papillomavirus (all genital papillomaviruses, PVs), β papillomavirus (e.g., PVs that cause epidermodysplasia verruciformis), and γ PVs (most of the viruses responsible for cutaneous lesions) [76, 77]. The importance of HPV has been escalated through the definitive association with cervical cancer, which is the second most frequently occurring cancer in women worldwide. HPV infections are frequent, but only a small percentage of infected individuals will retain the virus and become chronic or persistent carriers, and thus leading the path for the virus to stimulate epithelial cell proliferation, whether malignant or not. Subsequent to the virus entering the cell and viral proteins being synthesized, there is an exact, yet intricate, control of the cell machinery by the virus. HPV's oncoproteins, E6 and E7, are able to interfere with cell regulatory proteins and the cascade controlled by them; further, the viral proteins E1 and E2 initiate viral DNA replication. Each step of the involved interaction between the virus and its host cell is a possible target for the development of therapeutics. In addition to surgery, which is the basic approach for the treatment of most frequently observed HPV lesions, adjuvant therapies have been proposed and tested to complete or replace surgery, when needed [78]. Therapeutic agents that interfere with viral replication of HPV will be further discussed.

***Imiquimod*** Imiquimod is a member of new class of immune response modifiers, the imidazoquinolines, and it enhances both the innate and acquired immune pathways (mainly through the T-helper cell type 1-mediated immune responses) resulting in antiviral, antitumor, and immunoregulatory activities. It was first approved in 1997 for the topical treatment of external genital and perianal warts. The mechanism of action of imiquimod involves cytokine induction in the skin, which subsequently activates the host's immune system to recognize the presence of viral infection (or tumor), eventually to eliminate the associated lesion. It is postulated that imiquimod specifically stimulates a cell-mediated immunity response against HPV, and the fairly long time to clinical efficacy by imiquimod supports this [79, 80].

Indication for licensure of imiquimod came from a number of recently published prospective studies, which were double-blind, randomized, vehicle-controlled trials with different dosing regimens (1 and 5%: daily or 3 times per week for 16 weeks or until lesions cleared). Total elimination of warts was seen in 37–52% of those treated with 5% cream, 14–21% with 1% cream, and 0–11% with vehicle-control by intent-to-treat analyses. Other recommended treatment methods for genital warts are nonspecific and mostly physical or cytotoxic ablative methods, and thus latent HPV can stay behind in the adjancent tissue. There is a relatively high rate of recurrence (20–70%) in these other methods in comparison to imiquimod (0–19%) [81–83]. Furthermore, initial studies show encouraging results for the use of imiquimod for the management of HPV-related intraepithelial dysplasias (bowenoid papulosis/vulvar

intraepithelial neoplasia) in both immunocompetent and immunocompromised patients [84, 85].

***Cidofovir*** Cidofovir is a nucleotide analog with broad spectrum antiviral activity against DNA viruses. Unlike other DNA viruses, HPV does not encode for its own DNA polymerase, the final target of cidofovir. Thus, it is not intuitive to use cidofovir for the treatment of HPV infection. Preliminary results of cidofovir in animal models indicated that cidofovir was able to provide some therapeutic results for the treatment of PV-induced lesions [86]. The first documented patient ever treated with cidofovir, in 1995, had hypopharyngeal/esophageal HPV lesions induced by types 16 and 18, which had failed laser treatment. The lesions regressed gradually and eventually disappeared with repeated cidofovir treatments [87]. Subsequent patients, with recurrent respiratory papillomatosis (RRP), have been treated with cidofovir with remarkable results [88–93]. Cidofovir has also been used for the local treatment of external HPV lesions in both immunocompetent and immunocompromised patients. Reported uses are limited series or case reports [94–102]. One placebo-controlled trial study revealed cidofovir superior to the placebo control in the treatment of condyloma acuminata in immunocompetent individuals [101]. Another study reported that cidofovir was able to partially or completely inhibit cervical dysplasia lesions only after three applications [103]. Other applications of cidofovir have included bowenoid papulosis, recalcitrant warts (including plantar warts), and other mucocutaneous HPV lesions that do not respond to conventional therapies [104]. Although further studies are needed to elucidate the exact mechanism of action of cidofovir in HPV-transformed cells, it has been demonstrated that cidofovir has an antiproliferative activity and it stimulates apoptosis in HPV-positive cell lines in vitro [105–109]. Topical cidofovir is not commercially available; however, it can be compounded at a local specialty pharmacy.

***Acyclovir and Ribavirin*** Both acyclovir and ribavirin have been used systemically (acyclovir) and injected locally (ribavirin) as therapeutic agents of severe RRP. Only limited reports exist and no control studies have been planned to date [89].

***Therapeutic Investigational Drugs*** In addition to cidofovir, there are several other acyclic nucleoside phosphonates, for instance, 9-(2-phosphonylmethoxyethyl) guanine (PMEG) and 9-(2-phosphonylmethoxyethyl)-$N^6$-cyclopropyl-2,6-diaminopurine (cPr PMEDAP), which, similar to cidofovir, are capable of specifically inducing apoptosis in HPV-infected cells. PMEG and cPr PMEDAP are being studied for the possibility of using them as therapeutic agents of HPV-associated papillomavirus lesions [105]. Molecules targeting HPV transcripts, including ribozymes, antisense oligonucleotides [110], and RNA interference-mediated genes are under investigation for their ability to inhibit the expression of HPV E6 or E7 oncogenes [111, 112]. Several therapeutic vaccines targeting the treatment of precancerous lesions and invasive carcinoma of the cervix, anus, and vulva, and juvenile respiratory papillomatosis are in different stages of development [113]. The rationale behind the vaccine is to target the oncoproteins since the continued expression of E6 and E7 is necessary to avoid apoptosis and cell cycle arrest and thus to sustain cells in a transformed state [78]. Results have been hopeful and at the same time discouraging [114]. A possible cause of the disappointing results could be that patients enrolled in the study were at an advanced stage of cervical disease, which is identified as being linked with genetic instability, viral immune escape, viral antigen tolerance, and downregulation of major histocompatability classes (MHC) class I alleles [114].

## 6 ANTIVIRALS FOR POXVIRUS INFECTIONS

The family of poxviruses includes the orthopoxviruses (e.g., variola, vaccinia, monkeypox, and camelpox), parapoxviruses (e.g., orf), and molluscivirus (e.g., molluscum contagiosum virus). Smallpox and molluscum contagiosum infect humans, and, although smallpox was eradicated in 1980, there are concerns now over bioterrorism [115, 116]. Furthermore, monkeypox, a rare zoonosis with a more recent outbreak in the midwestern United States, demonstrates the continuing need for development of effective therapies against poxviruses [117]. Antiviral drugs as a therapeutic regimen for poxviruses offer a combination of chemical stability and ease of delivery that is enticing from a public health viewpoint.

***Cidofovir*** Cidofovir, an acyclic nucleoside phosphonate, is currently licensed against cytomegalovirus (CMV) retinitis and is believed to work by inhibiting the cytomegalovirus DNA polymerase, a target common to both CMV and poxviruses. In addition, cidofovir has antiviral activity against poxviruses in vitro and against cowpox and vaccinia viruses in mice [118–120]. It is also thought that cidofovir inhibits the exonuclease activity of proofreading, and subsequently generating error-prone DNA synthesis during poxvirus replication [121]. This agent was used successfully in the treatment of molluscum contagiosum in AIDS patients, where it was administered topically or intravenously (at 2 or 5 mg/kg

every 2 weeks). This resulted in regression of lesions within 2–4 months of therapy [122, 123]. Cidofovir has also proved to be effective in the topical treatment of orf (ecthyma contagiosum or sheep pox) with complete resolution of the lesions subsequent to seven courses (2–3 months) [124].

***Therapeutic Investigational Drugs*** Several nucleoside analogs (e.g., S2242, 8-methyladenosine, and idoxuridine) and nucleotide analogs (e.g., HPMPDAP, (S)-HPMPO-DAPy, and adefovir) are effective in various animal models of poxvirus infections [125, 126]. Since smallpox has been eradicated and infections with monkeypox are very rare, it is difficult to study these selected agents. Thus, it is important to study these promising drugs in animal models and in related poxvirus infections (e.g., molluscum contagiosum or ecthyma) [125].

## 7 ANTIVIRALS AGAINST INFLUENZA VIRUS INFECTIONS

There are three influenza viruses: A, B, and C; only A is further subdivided and five of those subtypes are known to affect humans. The persistent epidemics of influenza A strains $H_3N_2$ and $H_1N_1$ and the possibility of a pandemic with avian influenza A strain $H_5N_1$ along with the fact that there is no existing vaccination for the latter has given much importance on treatment (and prophylaxis) of influenza virus infections. Four approved drugs from two drug classes are available as therapeutic and prophylactic agents in the United States. They include the adamantanes, amantadine and rimantadine, and the neuraminidase (NA) inhibitors, zanamivir and oseltamivir [127–129].

***Adamantanes*** Amantadine and rimantadine are matrix (M2) hydrogen ion blockers that have been used for many years. The target of the adamantanes, the M2 ion channel, is specific to influenza A viruses, and thus the adamantanes are active only against influenza A. The adamantanes have proven prophylactic efficacy in prior influenza pandemics and are more cost effective if the virus is susceptible. However, in the past there have been concerns of emergence of drug-resistant virus mutants, and thus the potential usefulness of adamantanes in future pandemics is unknown. Furthermore, amantadine, in particular, has adverse side effects on the central nervous system [127, 129].

***Neuraminidase Inhibitors*** NA inhibitors are active for the therapy and/or prophylaxis of both influenza A and B. Influenza virus has a distinct replication strategy where it uses one of its surface glycoproteins, hemagglutinin (H), to attach to the target cell receptor, which contains a terminal sialic acid (*N*-acetylneuraminic acid), and another surface glycoprotein, neuraminidase, to cleave off the terminal sialic acid of the host cell receptor, permitting the virus particles to leave the cells after viral replication has completed [130, 131]. NA inhibitors prevent the release of the newly formed virus particles, subsequently impeding the spread to further host cells. Advantages offered by NA inhibitors are considerable. In therapeutic terms, they lessen the illness in 1–2 days, reduce virus transmission to household or health care contacts, and lessen the frequency and severity of complications (e.g., sinusitis and bronchitis). When used prophylactically, they substantially lessen the number of new cases of influenza. Resistance to NA inhibitors can occur [132], but there is no direct evidence thus far [133]. Oseltamivir, which is conveniently administered as oral capsules, should be stockpiled to affront a possible influenza A epidemic in the future [127].

***Therapeutic Investigational Drugs*** Investigational antiviral agents include new NA inhibitors (peramivir and A-315675), long-acting topical NA inhibitors, conjugated sialidase, hemagglutinin inhibitors, small interfering RNA, polymerase inhibitors, and protease inhibitors. Topically applied long-acting NA inhibitors that exert activity for a longer duration in animal models are also under investigation. Furthermore, early in vitro studies assessing combination regimens demonstrated that ribavirin in addition to an M2 ion channel inhibitor had superior action against influenza A [134]. Subsequent combination therapy trials done, notably with rimatidine and subsequent zanamivir treatment, showed less adamantine resistance in the cohort receiving both agents [135]. However, the combination regimen of an NA inhibitor and adamantine would not be effective against viruses that are already adamantine resistant. Additional studies are needed to assess combination regimens, including those investigating dual NA inhibitors, and transcriptase inhibitors (e.g., ribavirin) combined with NA inhibitors. In addition to the already approved use of ribavirin in combination therapy in HCV infections, it is also indicated as small-droplet aerosol treatment of respiratory syncytial infections (RSV) in infants.

## 8 CONCLUSION

The past 15 years have seen significant progress in developing new antivirals. In 1990, there were just five drugs licensed as antiviral agents, whereas now there are approximately 40 drugs in the antiviral market

repertoire, most being for the treatment of HIV. Nonetheless, combination therapy has only augmented life expectancy for individuals with advanced AIDS from 1.53 to 2.91 years [136]. Evidently, novel therapies with different mechanisms of action and distinct resistance profiles continue to be greatly needed. In addition to HIV/AIDS, there is also an essential need for novel agents against other viral pathogens since treatment options tend to be more limited. In the investigational agents reviewed in each section, the most success is likely to be obtained with combination regimens, especially in the treatment of chronic viral infections, such as HIV, HBV and HCV [131]. Over the years, one of the main attributes sought in a new antiviral is the capacity to treat patients who have developed resistance to existing treatments, and numerous compounds are investigated in such advanced-stage patients. The main need for antiviral agents, past, present, and likely in the future continues to be in the world's poorest countries [136].

# HIGH-THROUGHPUT SCREENING FOR SMALL-MOLECULE DRUG DISCOVERY

C. Parker and J.-H. Zhang

*Lead Finding Platform, Novartis Institute for Biomedical Research, Cambridge, Massachusetts*

## 1 INTRODUCTION

There is ample evidence that high-throughput screening (HTS) has become one of the main methods for generating leads for drug discovery [1]. The capacity and throughput for screening has been growing steadily for the last two decades. HTS has transformed biological testing from a process using test-tube and cuvette measurements to one using high-density, low-volume assay formats and screening systems. This transformation has been in response to rapid changes in biological target identification and validation, facilitated by advances in genomic and proteomic studies and compound synthetic methodologies. Particularly, the development and utilization of miniaturized, homogeneous assay technologies and various signal detection methodologies has made possible the screening of hundreds of thousands and even millions of compounds in a relatively short time period. Assay format standardization, instrumentation automation, assay miniaturization, and informatics tools for data analysis have greatly facilitate the screening process by increasing reliability and reducing personnel workload. Biomolecular screening has become a fast growing and critical field in early drug discovery. With the demands for ever-increasing productivity in drug discovery and development, one can only expect that the emphasis on discovering drug candidates faster and of higher quality will increase. These demands impose new challenges and also present new opportunities for the field of HTS and its related drug discovery activities.

There are many different drug discovery strategies where HTS can be applied, from the conceptually simple "screen everything we have" strategy to various strategies that call for the screening of subsets of compounds chosen to fulfill a defined hypothesis [2]. Although every strategy has its own advantages and disadvantages, they all require compounds or samples to be screened for biological activity in an efficient and reliable manner. The involvement of HTS activities in different phases of drug discovery and development are shown in Figure 1.

In a broader view, HTS should not be regarded as a specialty field, only performing assay development, method validation, and screening. HTS has become more of a collective term for a range of multidisciplinary activities, ranging from the creation of cell lines or recombinant enzymes for screening to computational and medicinal chemists designing and making screening compound libraries, and from engineers creating suitable robots and instrumentation allowing the automation of biological assays to statisticians and modelers who help analyze screening data to extract useful and predictive models of mode of interaction. Figure 2 illustrates the interconnection of scientific disciplines required for successful HTS and hit-to-lead optimization processes.

There are two major assay types in HTS, biochemical and cell-based assays, as will be illustrated in the following section. For any specific target, there are usually several assay formats available. In the past, assays involving the use of radioactive isotopes had been used

routinely. Although radioactive assays are very sensitive and reliable, more and more nonradioactive assay formats are being employed in HTS in recent years to avoid the added safety issues and inconvenience of handling and disposing of radioactive materials. Assay formats not requiring separation steps, that is, homogeneous assays such as time-resolved fluorescence resonance energy transfer (TR-FRET) (or referred to as homogeneous time-resolved fluorescence [HTRF]), fluorescence polarization (FP), AlphaScreen, scintillation proximity assay (SPA), and chemiluminescence (e.g., HitHunter™ cAMP detection) have become popular formats in HTS. For cell-based assays, several common assay formats are reporter genes (luciferase, etc.), Fluorescence Imaging Plate Reader (FLIPR), Cytoblot™, and high content imaging (HCI). Some newer assay formats based on label-free detection [waveguide sensing, cell electronic impedance, liquid chromatography/mass spectrometry (LC/MS)] will emerge as potentially preferred assay formats in the coming years (see Section 6 of this chapter for more details).

The challenge facing HTS scientists is not only that an assay developed for a target must be biologically relevant and as specific as possible, but that HTS is also limited by practical constraints such as cost, scale, and throughput. An HTS must be properly designed and configured to maximize both screening efficiency and biological effectiveness. An improperly designed HTS assay may fail to detect the desired classes of hits even if it is trivial to execute. Moreover, drug screening can only be successful when the compound libraries interrogated are populated with druglike (or leadlike) molecules so that the identified active compounds can be evolved into lead compounds with suitable absorption, distribution, metabolism, and excretion (ADME)

properties for later drug development. In the last decade, the number of new chemical entities entering the medicinal marketplace has not increased as fast as would be expected given the increased capacity of HTS. Therefore, the HTS should be coupled more to pharmacological properties in order to make screening more relevant and predicative.

The aim of this chapter is to review some of the HTS processes in current drug discovery, including assay technologies and screening strategies, the steps taken in assay development and validation, the screening process, and commonly used quality control measures. Also highlighted in this chapter are the analysis of HTS data and some of the approaches used for data mining for finding lead series. Finally, the chapter reviews some of the emerging trends occurring in the science of biomolecular screening.

## 2 TYPES OF HTS ASSAYS

High-throughput assays can be used to probe different levels of molecular interactions in a continuum of complexity, ranging from simple molecular binding events to effects at the cellular or even whole organism level. These assays can be classified in several different types. Broadly speaking, there are two major assay types in HTS: in vitro biochemical and cell-based assays. The biochemical assays can be further divided into molecular binding (affinity) and in vitro functional assays (e.g., enzymatic reactions). There is sometimes, however, no clear distinction between the affinity binding and in vitro functional assays. For example, ligand-induced GTPγS binding to G proteins can both be regarded as a binding or a functional assay. A second example is the ligand-activated coactivator recruitment to the ligand-binding domain of a nuclear receptor. Cell-based assays can also further divided into cell- or membrane-based binding assays and functional cell-based assays (Fig. 3). This section is an overview of the assay technologies commonly used for HTS. Some newer trends will be discussed in Section 6 at the end of the chapter.

### 2.1 In Vitro Biochemical Assays

In modern HTS, in vitro biochemical assays have been used extensively against various targets, for example, enzymes, receptor–ligand, and protein–protein interactions. This reductionist approach has been facilitated by various biochemical and genetic studies for delineating complicated metabolic, signal transduction pathways, and biological systems involved in disease. It offers the advantage of clear drug–target interactions, leading to clean structure–activity relationship (SAR) during hit-to-lead optimization. The drawbacks of this approach include sometimes a lack of physiological context, compared to cell-based assays, which can lead to a lack of in vivo efficacy. A clear trend is to combine both approaches so as to gain the advantages of biochemical and cell-based screens while minimizing the risks.

Molecular binding interactions are fundamental to biological processes and together with enzymatic assays have formed the backbone of HTS assays for drug discovery. Targeting of specific enzymes and components in signal transduction, metabolic pathways, protein processing, and inflammatory cascades has proven to be a valid approach for addressing disease processes. Many classes of therapeutically relevant enzymes have been actively pursued using HTS for lead generation. The majority of these enzymatic assays have been adapted in miniaturized microplate format, automated, and used for compound screening or even mutant enzyme screening.

**Figure 3** Hierarchy of assays monitoring biological processes of increasing molecular complexity.

Several of the most commonly used high-throughput assay technologies based on direct molecular affinity binding events and enzymatic activities are highlighted below. Many of these assay and detection technologies can be used to measure both binding and enzymatic activities. Several reviews on HTS assays are available, for example, the books edited by Seethala and Fernandes [3] or Janzen [4] contain many excellent review articles.

***Fluorescence-Based Assays*** Currently, the most commonly used detection methods for high-throughput screening are fluorescence based, as these readouts are sensitive, usually homogeneous, and can be readily miniaturized, even down to the single molecule level [5]. Fluorescent signal can be detected by methods such as fluorescence intensity (FI), FP, fluorescence resonance energy transfer (FRET), TR-FRET, and single-molecule techniques such as fluorescence intensity lifetime and fluorescence correlation spectroscopy (FCS). These homogeneous assay formats are "mix and read" type of assays that allow high throughput and assay miniaturization.

*Fluorescence Intensity Assays* These assays measure fluorescence intensity change using fluorogenic substrates or internally quenched substrates. The enzymatic reaction generates a fluorescent product or releases quenching effects on the substrate. These assays are used mostly extensively for hydrolase assays, such as protease assays (e.g., [6]).

*FRET Assays* Fluorescence resonance energy transfer occurs when donor (D) and acceptor (A) molecules are brought in close proximity (e.g., 10–60 Å), with sufficient energy overlap and parallel in transition dipole orientation [7]. FRET can be measured as the quenching of donor fluorescence by an acceptor or as the sensitized fluorescence emission of an acceptor. Some D/A pairs are the 5-(2-aminoethylamino) naphthalene-1-sulfonic acid (EDANS)/4-(4-dimethylaminophenylazo) benzoic acid (DABCYL) with typical Föster radius ($R_0$) of 33 Å and the fluorescein/tetramethylrhodamine pair with an $R_0$ value of 55 Å. FRET assays have been developed for a variety of different target types, such as protease or kinase assays [8].

*TR-FRET Assays* TR-FRET assays have been commercialized under a number of different acronyms, including: HTRF (CisBio), LANCE (Perkin-Elmer), and LanthaScreen (Invitrogen): The assay principle is similar to FRET, that is, based on fluorescent resonance energy transfer from a fluorescent donor moiety (D) to an acceptor moiety (A) when A and D are brought into close proximity. The difference is that TR-FRET involves time-resolved fluorescence (TRF), based on the long fluorescence lifetime properties of certain lanthanide ions, for example, europium (Eu), terbium (Tb), and samarium (Sm). An added advantage of these lanthanide ion chelates is their relatively large Föster radius (~100 Å), allowing energy transfer over distances greater than for many other FRET pairs. The europium complex (D) paired with any of the allophycocyanine (APC), XL665, or Cy5 acceptor dyes or the terbium (D) paired with fluorescein (A) are frequently used to probe in vitro receptor–ligand and protein–protein interactions. The receptor–ligand or protein–protein interaction or other binding partners can be directly covalently linked to one of the A/D moieties or indirectly via A/D-conjugated antibodies or biotin/avidin binding. This homogeneous assay technology is widely used in binding and enzymatic assays [9–11] and can also be used for detection of cell metabolites for cell-based assays [12] .

*Fluorescence Polarization Assays* FP is a homogeneous assay format for the determination of molecular interactions in solution. When a fluorescent molecule is excited with polarized light, the degree to which the emitted light retains that polarization is proportional to the molecule's rotational relaxation time. Small fluorescent molecules rotate faster in solution and give a low polarization value, while large fluorescent molecules rotate slower and give a high polarization value. Both polarization and anisotrophy can be used to measure the molecular interaction in solution. In HTS, polarization (P) is defined as $(I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp})$, where $I_{\parallel}$ and $I_{\perp}$ represents the fluorescence intensity parallel and perpendicular to the incident light, respectively. The polarization value is usually expressed as milli-P (mP:1/1000 of 1 P unit). The FP signal is between 0 and 500 mP for solution samples and is in the range of 40–300 mP for many HTS assays experimentally. Even though in many cases the milli-P change is used to calculate the binding or product conversion, it should be noted that the FP signal is not directly proportional to the concentration of the large fluorescent moiety. Therefore, a standard curve is needed to convert the milli-P values to the concentration of the related specific fluorescent molecules. Fluorescence polarization is suitable as a detection method when the mass of the fluorescently labeled tracer changes during binding or enzymatic events [13]. Constraints on the lifetime of the fluorescence of most labels makes FP less suitable for probing interactions between two large macromolecules.

Some of the following fluorescent detection technologies have also been used in HTS, albeit less commonly than the above-mentioned technologies.

*Fluorescent Correlation Spectroscopy* In FCS, a laser beam focuses on a very small volume (femtoliter) in a solution and monitors spontaneously fluctuating fluorescence molecules in a statistical manner. The diffusion time and brightness of the fluorescence molecules reveal binding or reaction activity information. FCS is suitable for ultra-low-volume HTS (uHTS) assays [14].

*One- and Two-Dimensional Fluorescence Intensity Distribution Analysis (FIDA)* Similar to fluorescent correlation spectroscopy, one- and two-dimensional (1D and 2D) FIDA use Evotec's confocal fluorescence readouts. Besides being able to distinguish different fluorescent species (e.g., bound and unbound labeled molecules) in one sample, these technologies measure and simultaneously determine multiple, species-resolved parameters, such as particle number (concentration) or molecular brightness (i.e., fluorescence count rate per particle) or anisotropy. These parameters can be used to distinguish real hits from false positives, including artifacts induced by autofluorescent compounds, biological reagents, and technical errors [15]. Both in vitro receptor binding and enzymatic reactions can be detected in these formats.

*Fluorescent Microvolume Assay Technology (FMAT)* FMAT is a bead-based or cell-based fluorescent technology for nonseparation detection. In FMAT, a laser beam is focused on the bottom of the well of the assay plate and fluorescence intensity of beads (via binding to fluorescently labeled molecules) is detected over the unbound and background fluorescence in solution. FMAT can be configured as a bead-based or cell-based assay for detection of specific biomolecules in solution or receptors on the cell surface. Up to two different analytes can be detected with appropriate fluorophores and detection setup [16].

*Luminex Assays* This assay technology is a bead-based, nonseparation technology using the Luminex color-coded beads and detection systems (Luminex 100 IS or Luminex HT). The readers used for this assay format are based on the principle of flow cytometry. The system enables assays to be multiplexed, that is, to allow one to simultaneously measure different analytes. The Luminex HT system is compatible with 96- and 384-well microplates, allowing rapid and cost-effective bioassays [17]. The throughput of the reader is still currently a limiting factor for large-scale HTS.

*Heterogeneous Fluorescent Assays—TRF or Delfia Assay (Dissociation-Enhanced Lanthanide Fluoroimmuno Assay)* This assay format uses time-resolved fluorescence in combination with enzyme-linked immunosorbent assay (ELISA)-like analyte capture methods. After washing the captured fluorescent molecules on the surface or beads, the bound molecules can be detected by TRF. This assay format yields very high detection sensitivity with low background [18]. It is essentially an alternative version of ELISA or ELISA-like assays, without the use of conjugated enzymes for detection.

***Luminescence-Based Assays*** Luminescence detection has the advantage of very low background over fluorescent technologies. Hence, the sensitivity of the assay can be extremely high. The following section highlights several assay technologies based on luminescence, including chemiluminescence and electrochemiluminescence.

*AlphaScreen Assay* The AlphaScreen assay format is somewhat similar to TR-FRET assays and is another versatile, nonseparation screening technology. It is a bead-based, chemiluminescent assay technology. The donor beads contain a photosensitizer that absorbs light at 680 nm and converts molecular oxygen to its excited singlet state. The accepter beads contain thioxene derivatives that react with singlet oxygen, generating chemiluminescence at 370 nm, which then excites fluorophores in the same beads, emitting light at 520–620 nm. The effective distance from donor to acceptor beads is ~200 nm in aqueous solution, much larger than that in TR-FRET assays. Another feature of AlphaScreen is that the amplification of the signal is huge, offering a better sensitivity than TR-FRET assay format. However, the amplified signal may carry a higher variability compared to TR-FRET assay format [19]. Both TR-FRET and AlphaScreen assay formats can be used not only for many in vitro binding or enzymatic assays but also to probe cell lysates for detection of secondary messengers or specific proteins [20].

*Electrochemiluminescence (ECL) Assay* This is a bead-based electrochemiluminescence assay using the Origen technology platform. ECL utilizes ruthenium chelates conjugated to antibody as a tracer, which reacts with tripropylamine (TPA) and emits luminescence upon application of a low voltage. Magnetic beads are utilized to align the beads to the surface of an electrode. This assay has been mostly used in diagnostic bioassays but also developed for HTS use [21].

*Other Luminescence-Based Readouts* Chemiluminescence detection methods based on enzymes such as horseradish peroxidase have been used as improvements to standard ELISA-based assays. The number of different luminescence-based assays has been expanding. For example, the Kinase Glo assay format monitors

the levels of adenosine triphosphate (ATP) remaining in a reaction mix. While this is originally developed for assaying of kinase targets, it could be easily adapted to monitor any ATP-consuming (or generating) reaction [22]. Recently, additional luminescence assay formats have been developed using substrates that liberate luciferin upon action of the target enzyme and have been applied to proteases, such as caspases [23] and cytochrome P450s [24].

***Colorimetric and Chromogenic Assays*** Colorimetric assays are not used as frequently in high-throughput settings as fluorimetric assays for several reasons. First, colorimetric detection is usually less sensitive than the more widely used fluorimetric detection, due to the dependency of the readout on the path length of light passing through the liquid sample (Beer's law). This issue poses a limit to the miniaturization of assays into lower volumes. However, it should be noted that clever methods to increase the apparent path length of light have been used to allow absorbance-based assays to be miniaturized even into 1536-well plate formats with reaction volumes of only 10 μL [25]. The second constraint on colorimetric assays is that colored compounds that are present in most large compound libraries interfere with detection, leading to screening artifacts. This issue can be overcome by monitoring the enzyme reaction rate over time instead of using an endpoint readout. The change in reaction rate is not so greatly influenced by the presence of colored compounds, as has been shown in screening using the relatively weak absorbance of reduced nicotinamide adenine dinucleotide phosphate (NADPH) [26] or the weak absorption of nitrophenolate [27].

***Coupled Assays*** Coupled assays have been used to monitor a variety of different enzymatic assays and can be split into two types: chemically coupled and enzymatically coupled assays. In the former type, the product of the enzymatic reaction under study is detected by reaction with a reactive chemical to allow easy detection of the analyte of interest. Examples of such assay format include the so-called adrenaline assay for the detection of compounds that can react with sodium periodate, which then reacts with adrenaline to generate a colored product [28] and the detection of free thiol groups by Ellman's reagent [5,5′-dithiobis(2-nitrobenzoate) or DTNB].

In enzymatically coupled reactions, the products or substrates of the reaction of interest are acted upon by a second enzyme, creating a tangible readout. One advantage of this kind of assay format is that the development of such a standard detection method can be used to monitor the activity of a family of enzymes utilizing a common analyte. Examples of such coupled enzyme assays include the detection of S-adenosyl-L-homocysteine (SAH) [29] and the detection of phosphate or $H_2O_2$ via the generation of highly fluorescent resorufin from Amplex red [30]. Recently, this strategy has been extended with a coupled assay system that detects the generation of adenosine 5′-diphosphate (ADP) rather than just phosphate [31]. The disadvantage of these coupled assay systems are that rigorous counterscreens are required to eliminate hits not acting directly upon the primary enzymatic reaction of interest.

One of the areas of assay development that has seen increased application is the use of enzyme complementation assays. While this has primarily been used in cell-based assays, a number of interesting applications of enzyme complementation for in vitro assays have been reported as well [32]. We will also discuss some of these assays under Reporter Gene Assay below.

***MS-Based Detection*** Recently, mass spectrometry coupled with LC/MS-based detection has been shown to be a new and valuable label-free detection tool for HTS. By measuring mass-to charge ($m/z$) ratio of analytes, MS-based assays have the advantage of allowing generic, label-free detection of reaction substrates and products. A group at Biotrove has reported the use of LC/MS setups for HTS [33] , and Zhang [34] has recently reported the successful screening of several metabolic enzymes with LC/MS detection in a large industrial screening scale. Several strategies have been used to increase the speed of LC/MS analysis, which has been the bottleneck of this screening system. These include utilization of four parallel LC units in either multiplexed electrospray (MUX) or serial gradient configurations, and the use of orthogonally pooled matrices of a small number of compounds, for example, 10 compounds per mixture, where each compound is tested twice in two different mixtures. These strategies have been proven to work well, and the analysis of near a million compounds can be achieved in 6–8 weeks. So far, large-scale LC/MS-based screening has been limited to in vitro enzymatic reactions. Other desorption-based MS detection techniques for HTS applications are currently in early stages of development and hold great promise [35]. MS-based HTS will play an increasingly important role in the HTS paradigm in the coming years.

***Microcalorimetry and Thermostability Methods*** Microcalorimetry monitors molecular interactions such as ligand binding by monitoring the enthalpic response of interaction. Typically, isothermal titration calorimetry (ITC) and differential scanning calorimetry (DSC) have been used to measure the binding constants and ther-

mostability of the protein–ligand complex. However, these traditional microcalorimetric methods have a very limited use in screening due to low throughput and high protein consumption. Currently, only a few thermostability-based methods have been modified to allow screening of compounds with reasonable throughput. The patented ThermoFluor affinity screening method is based on the fluorescence change seen upon binding of a specific dye to native protein versus. a denatured form of the protein. This assay technology has been shown to have a higher throughput and relatively lower protein consumption than traditional microcalorimetry methods [36–38]. Other approaches measure the change of fluorescence during the denaturation of a protein at a set temperature and the effect of ligands in altering the rate of denaturation [39] or measure light scattering of these transitions [40]. Techniques to improve the throughput of these approaches include enthalpy arrays [41]. However, the current methods still suffer from the relatively high protein concentration (micromolar range) needed to monitor the ligand effect and their low throughput, compared to many other HTS assay formats.

***Radioisotope-Based Assays*** It has been anticipated for some time that biological assays based on radiolabeled substrates or ligand would be used less frequently in HTS [42]. However, the specificity with which substrates and ligands can be labeled with a radioisotope without perturbing their chemical properties and the high detection sensitivity of these assays continue to ensure that assays using radioactive tracers remain an important tool for HTS assays. A number of well-developed technologies based on scintillation proximity, such as SPA beads [43] or FlashPlates [44], allow complex biological assays to be conducted without the need for time-consuming separation steps (e.g., [45]). Technological advances such as the use of detection methods based on charge-coupled devices (CDD) that monitor the activity of a whole assay plate at once have reduced the time required for conventional scintillation counting. These CCD-based plate readers, such as the LeadSeeker and ViewLux, also have the advantage that they allow the miniaturization of assays to the 1536-well formats [46]. Other than the commonly used SPA and FlashPlates assay formats, traditional filter binding assays continue to be used for specific occasions.

***Chromatography-Based Assays*** *Affinity Selection Chromatography* The use of chromatography to separate the bound and unbound ligands constitutes an intuitively simple method for detection of ligand binding to a large biomolecule. Similar methods have been used previously for detection and characterization of small-molecule binding to serum albumin [47]. This general approach has been utilized and developed for HTS by several laboratories. One embodiment has been a method named SpeedScreen in which size exclusion chromatography (SEC) has been used to separate bound and unbound ligands from pools of small molecules [48]. The compounds bound to the protein of interest are then subjected to LC/MS analysis and identified by their mass. The SpeedScreen method has been automated, and increased throughput has been obtained by parallel processing of the SEC steps. A second method has taken a very similar idea; but instead of using SEC, it uses a size exclusion ultrafitration step such that the protein–ligand complex remains trapped in the filter plate rather than flowing through it [49]. Yet another slightly different approach has been reported [50] in which traditional SEC is used to separate bound and unbound ligands. This approach has not been formatted to allow parallel processing of multiple samples as is possible with the plate-based methods just described for Speedscreen. However, this screening method has been extended to allow screening of integral membrane proteins such as G-protein coupled receptors (GPCRs) [51].

***Immobilization-Based, Label-Free Detection Techniques*** The immobilization-based, label-free techniques have a variety of approaches and strategies: some in which binding is detected in a subsequent step by a labeled antibody or aptamer and some in which binding is detected by changes in the surface properties of the immobilized target. The first type of immobilized assays includes ELISA and ELISA-like methods. These methods require the availability of selective labeled binding partners such as antibodies or oligonucleotide aptamers for the protein of interest (for a review see [52] ).

One original embodiment of surface property-based detection methods was the Biacore instrumentation in which surface plasmon resonance (SPR) technology is used to detect molecular interactions with the immobilized target (reviewed by [52b]). In the last few years, label-free detection systems and technologies for in vitro and cell-based assays have emerged as a new detection paradigm in HTS and related applications [53]. These include the development of evanescent wave technologies that have been adapted to allow the detection of binding at the surface of microtiter plates, such as the Bind system from SRU, Corning's Epic system, and Fortèbio's Octet system. Still other methods have been developed, such as the use of acoustic sensing [the Resonant Acoustic Profiling (RAP) system from AccuBio] or wavelength-interrogated

optical sensing (WIOS, developed by CSEM Scientific). In these detection strategies, the change in surface molecular properties is dependent on the size of the ligand interacting at the immobilization surface [37]. Some of these technologies are already adapted into 384-well plate format for HTS applications.

Another approach that has been reported for monitoring the effect of small-molecule binding to proteins is frontal affinity chromatography (FAC) coupled with MS detection (FAC-MS), first reported by Hage [54] and recently reviewed by Slon-Usakiewicz and coworkers [55]. In this approach, the protein or target of interest is immobilized in the column matrix, and the ligands of interest are infused into the column with buffer and pumped through the column. If a compound has affinity for the immobilized protein, it will tend to be retained on the column, delaying the time it takes for the compound to be eluted. The higher the affinity the compound has for the immobilized protein, the longer it will take before it is eluted from the column. Compounds eluted from the column are detected by mass spectroscopy. In this approach it is possible to screen in mixtures, as long as the component compounds have unique mass-to-charge ratios for mass spectrometric detection, and compounds elute according to their relative affinity. Thus, the relative ranking of ligand affinities in the mixture can be assessed in one experiment. The drawback of this approach, as with all techniques requiring immobilization, is that sufficient protein has to be immobilized onto the column and immobilized in a way that will not inhibit or influence the binding of small molecules.

## 2.2 Cell-Based Assays

Cell-based assays have been important sources of drug candidates from the days of screening natural product extracts for antibacterial activity [56]. However, with the development of molecular biology and advanced methods for cell culture, many more ways to monitor specific biological processes in cultured cells have become available. The use of cell-based assays in drug discovery and in HTS has increased steadily in the past several years. Cell-based screening in which the target activity is directly assessed in its cellular environment can improve the quality and biological relevance of active compounds in comparison to isolated biochemical target-based screening. Various cell-based assays such as reporter gene assays, secondary messenger assays, cell-based ELISA, cell-based proximity assays, and pathway screening assays are all used extensively in screening. Other assays use reporters to monitor the state and location of cellular constituents, by using specific binding reagents, or use indirect technologies that monitor nonspecific aspects of cellular growth, shape, or electrical conductivity.

***Reporter Gene Assays*** Reporter gene assays are assays that monitor changes in the intracellular levels of a particular gene. This method uses specific enzymes or fluorescent proteins whose expression level are linked to a promoter or ribonucleic acid (RNA) sequence that is believed to be regulated by expression of a gene of interest. Initially, this experimental strategy was used in bacterial systems using reporters that could be used in selecting for antibiotic resistance or nonselective reporter systems such as β-galactosidase or chloramphenicol acetyl transferase. Multiple reporter gene and cell lines have been used in antibiotic drug discovery [57] as well as to help define the mechanism of action of compounds [58]. While the development of novel reporter systems for bacterial systems has not been a major area of research recently, technology development for reporter gene assays in mammalian cell systems has continued, with a wide range of technologies now being available. Some of the more commonly used reporter assay systems are highlighted below.

*β-Lactamase* One of the recent improvements in the available reporter gene systems for mammalian cell assays was the development of the bacterial β-lactamase, *bla*, in conjunction with the CCF2-AM dye (a FRET-based fluorescent substrate from Invitrogen), that is, the GeneBlazer system. This cephalosporin-based dye contains a set of acetate ester groups that are removed by intracellular esterases, resulting in intracellular accumulation of the dye. The dye molecule contains a FRET pair allowing ratiometric estimates of *bla* activity. The system has been shown to work with a wide variety of different pharmaceutical targets including GPCRs [59] or to allow detection of antiviral compounds [60].

*Nitroreductase* A novel reporter system based on the use of a bacterial nitroreductase (NTR) has been developed with a cell permeate cyanine fluorescent dye, CytoCy5S, as its substrate. The nitro groups in the substrate can be reduced by the enzyme to generate a fluorescent product that is then retained within the cell [61]. The purported advantages of this reporter are the use of a red-shifted substrate, leading to less interference due to compound and cell autofluorescence. Also, the substrate CytoCy5S is reportedly more photostable in solution and is more soluble in water. However, the biggest difference of this system from the *bla* system may be that the product of the nitroreductase can reportedly be fixed, which can simplify scheduling issues in screening. Assay plates can be read up to 48 h following fixation, thus making NTR compatible with high-content imaging readouts.

*Secreted Alkaline Phosphatase* Another reporter gene commonly used to monitor the activity of promoter constructs is secreted alkaline phosphatase (SEAP). Although such constructs do not allow monitoring of the intracellular location of the proteins, there are a number of very sensitive chemiluminescense-based detection assays for SEAP, allowing very low levels of gene expression to be monitored. The secretion of the reporter gene as well as the stability of the SEAP reporter also allows the accumulation of signal over time to be monitored. Recently, a SEAP reporter-based system has been developed for screening for effectors of the signal peptide-associated protein co-translational translocation process [62].

*Luciferase* The most commonly used reporter gene systems are those based on luciferases. These assays have been widely accepted for a number of reasons, including the sensitivity and large dynamic range of the assay and the availability of photon multiplier tube (PMT)-based readers capable of monitoring luciferase readouts in most biology laboratories. The assay format has also been widely used in the screening community with the development of sensitive CCD camera detection systems that allow rapid reading of assay plates.

Different luciferase reporters can be used for sequential detection of two different promoters, such as the Dual-Glo readouts. Such readouts allow the simultaneous normalization and correction of assay signals from the gene of interest and a control gene. Recently, there have been further developments in this area with the availability of the Chroma-Luc system in which two versions of the click beetle (*Pyrophorus plagiophalam*) luciferase have been cloned into expression vectors. These enzymes are essentially identical except for one amino acid, which causes one version to emit a predominantly green light while the second mutant emits a predominantly blue light. The result is that with the addition of one detection reagent it is possible to monitor both the specific target signal as well as the control signal. However, the luciferase method has the disadvantage that the readout, made after lysing the cells, is a single destructive event. However, some luciferase systems can use substrates that allow nondestructive monitoring of luciferase activity such as coelenterazine for the Renilla luciferase [63] or luciferin with firefly luciferase [64], allowing real-time, noninvasive measurement of luciferase activity. Luciferase can also be used to detect close proximity of protein partners using bioluminescence resonance energy transfer (BRET) [65].

*Enzyme Complementation as Reporters* As mentioned earlier, enzyme complementation has been used to develop cellular assays predominantly monitoring the intracellular location of different protein partners or secondary messengers. Thus, these assays can monitor translocation events causing both fragments of an enzyme to be present in the same cellular location, leading to formation of the active enzyme. This principle has been used with luciferase enzymes for development of sensitive translocation assays [66]. Recently, a novel split-GFP (green fluorescent protein) system that consists of a small (GFP β strand 11; GFP 11) and a complementary large fragment (GFP β strand 1–10; GFP 1–10) has been reported [67]. Neither fragment by itself displays fluorescence, but GFP fluorescence emerges upon self-association of the two complementary fragments. This split-GFP may also be useful for detecting protein–protein interaction in vivo, similar to the luciferase fragment complementation systems.

*Fluorescent or Bioluminescent Proteins* Green fluorescent protein has been widely used as fluorescent tracers and reporters for cellular imaging and for high-content screening. Some GFP derivatives (such as YFP and CFP) can be used in BRET assays [68]. For example, to monitor GPCR activation, GPCRs and β-arrestin are re-engineered to incorporate derivatives of Renilla luciferase (Rluc) and green fluorescent protein (GFP2), respectively. The interaction of the GFP2 arrestin fusion with an agonist-activated Rluc-GPCR fusion brings Rluc and GFP2 into close enough proximity to allow resonance energy transfer to occur [69].

***Cell-Based ELISA*** Chemiluminescence detection methods based on horseradish peroxidase have been used as improvements to standard ELISA-based assays. This detection method has been extended to allow the development of cell-based Western blot assays, also termed Cytoblot assays [70]. In fact, this assay format can be seen as the precursor to a number of newer assay technologies that seek to perform immunodetection of analytes in whole cells, including assay formats such as the SureFire and Licor technologies [71].

***Cellular Imaging Analyses*** Fluorescent-based cell imaging techniques include fluorescent microvolume assay technology (FMAT), fluorometric imaging plate reader (FLIPR), high-content imaging, and some luminescence readers. FMAT has been already mentioned in Section 2.1. FLIPR readers have been widely used for mobilized $Ca^{2+}$ flux measurement elicited by activation of GPCR. The development of nonwash dyes (e.g., Calcium-4) and FlexStation or $FLIPR^{tetra}$ systems have made it possible to miniaturize such assays to 384- or 1536-well formats [72, 73]. The use of voltage-sensitive indicator dyes on the FLIPR also allows screening assays for some ion channels [74]. However, while

showing good correlation with manual patch clamp data, ion channel activity from FLIPR membrane potential assays are sensitive to compound interference. Unfortunately, the chemicals interfering with a particular channel are highly unpredictable (see discussion on more ion channel HTS assays below).

High-throughput flash luminescence readers enable functional GPCR and calcium channel testing. For example, cell flash technology (Lumax Flash HT) uses an intensified CCD camera that is able to detect the signals from all wells of a plate, with a 16-fold parallel noncontact dispenser injecting cells or reagents into the assay wells.

In high-content screening (HCS), automated microscopes take images of cellular models where the proteins of interest are detected because they bear a fluorescent tag, such as the green fluorescent protein (GFP), or they may be identified by fluorescent antibodies. Many HCS instruments are (fluorescence) microscopes that are connected to some form of image analysis package, such as the Arrayscan (Cellomics), Incell 1000/3000 (GE/Amersham Biosciences), OPERA (Evotec Technologies), and ULTRA (Molecular Devices). Alternative instruments, such as the Acumen Explorer or IsoCyte's BlueShift readers, do not take microscope images of the cells, but rather use lasers to scan the bottom of the plate, recording the peaks of fluorescence intensity from which a subsequent image is generated.

The primary advantage of such cell-based assays is that the selection of active molecules is based on a cellular phenotype. Therefore, the screen does not require a priori knowledge of any specific biochemical targets that are being affected by the active compounds. The ability to rapidly perform an HTS campaign based on cellular phenotype may be a benefit for the rapid discovery of novel and unexpected compounds, but this screening paradigm does create the issue of further defining the mechainsm of action of such active compounds.

***High-Throughput Flow Cytometry*** High-throughput flow cytometry has been implemented for HTS applications. The reported HyperCyt system interfaces a flow cytometer and autosampler. As the sampling probe of the autosampler moves from one well to the next of a multiwell microplate, a peristaltic pump sequentially aspirates sample particle suspensions from each well. Between wells, the continuously running pump draws a bubble of air into the sample line. This results in the generation of a tandem series of bubble-separated samples for delivery to the flow cytometer. Likewise, the time-resolved data is collected in a continuous stream, with the accumulated data from all wells of a microplate representing a single data file. As with many screening systems, maximum throughput is achieved when the HyperCyt system is used for endpoint assays. The platform can be applied to general cell-based assays and particle-based multiplexed approaches [75]. The advantages this system offers are the ability to use many preexisting flow cytometry assays/antibodies and the rich multidimensional result sets that have been developed for flow cytometers. The challenges that remain are the need for cells in suspension for the assays, the limited throughput of the system.

***Cell-Based Label-Free Readouts*** Some recently developed cell-based, label-free monitoring systems include electro impedance-based sensors, for example, the CellKey system based on cellular dielectric spectroscopy (CDS) or the RT-CES (Real-Time Cell Electronic Sensing) System (ACEA Biosciences), which enable comprehensive pharmacological evaluation of endogenous cell surface receptors and even nuclear hormone receptors. These sensor systems use noninvasive impedance-based measurements to detect the presence, absence, or change of properties of cells or molecules affecting the electronic properties and ionic passage on the sensor surfaces, allowing label-free, real-time, kinetic measurement of several types of receptors including GPCRs and tyrosine kinase receptors. In a similar manner, there are reports of evanescent wave technologies being used to allow the detection of cellular changes at the surface of microtiter plates [76].

For all of these systems, cells are grown in the individual, sensor-containing wells of the microtiter plates. Changes to the biological status of the cells are measured automatically in real time by these systems. Although these systems have been adapted to 96- or even 384-well plate formats, they have only limited throughput at present. In addition, direct interpretation of the results in terms of the underlying molecular events is still not possible. These assays can be used in target validation and as orthogonal assays for primary HTS hit evaluation.

***Cell Growth*** The simplest cell-based assay is to monitor cell growth and proliferation. While the majority of screening reports have focused on growth inhibition for antibacterial and antifungal activities, such methods have successfully been used to screen for compounds with anticancer activity, as reviewed by Boyd [77]. However, growth inhibition for cytotoxicity assays are usually used as secondary screening assays to characterize compounds for possible off-target effects.

Some advances on these commonly used assays now include systems to monitor multitarget screens. For example antimicrobial screens have been implemented by using the protection afforded by the active compounds to rescue mammalian cell growth [78]. Other

similar systems have been developed using novel model organisms, such as the co-culture systems developed by companies such as Athelas and others [79, 80]. Such assay systems have the potential to not only identify compounds acting to inhibit microbial growth but also compounds that act by interfering with bacterial mechanisms essential for in vivo survival and pathogenesis of bacteria.

***Assays for Ion Channels*** Ion channels are an important family of drug targets. The gold standard for ion channel assays has always been conventional patch clamp experiments. However, due to its low throughput and the high technical skill requirement to conduct such experiments, this method is not suitable for drug screening. Functional HTS for channels and transporters was not available until a few years ago, when calcium or membrane potential dye was applied in FLIPR assays to measure ion channel activities causing intracellular calcium [81] or membrane potential [74] change, respectively. While significant for being the first major true screens for ion channel targets, the shortcomings of the FLIPR-type assay are also obvious: (1) It is considered indirect and therefore many other factors that cause internal calcium or membrane potential change will bring false positives or false negatives; (2) as FLIPR is a fluorescent dye-based assay, a large number of compounds may interfere with the readout and give false readings; and (3) lack of direct control of voltage make such assays less informative and, perhaps, to some channels, less relevant.

The recent breakthrough technologies in automated electrophysiology, such as IonWorks Quattro, PatchXpress (Molecular Devices), and QPatch (Sophion Inc.), have profoundly changed the ion channel research field. These new automated electrophysiology platforms are able to fill the gap between FLIPR type of assays and conventional patch clamp assay, not only by significantly increasing the throughput but also by using more relevant controlled testing conditions. Although the throughput for such technologies is not high enough for primary screening as conventional HTS, it is feasible to run screens of smaller or focused compound libraries for ion channel targets with direct electrophysiology criteria, which maximize potential gain yet minimize the liabilities.

## 3 ASSAY DEVELOPMENT AND VALIDATION FOR HTS

The previous section reviewed a variety of assay types that are commonly employed in HTS. Often there is a wide choice of assay technologies that can be used for design and implementation of any particular assay. An HTS must be properly designed and configured to maximize both screening efficiency and biological relevance. There are some generally accepted principles, or guidelines, for HTS assay development, including the biological relevance of the assay, assay specificity, assay sensitivity and signal dynamic range, linearity of the assay signal, technical ease (which will impact the throughput of the assay for large-scale screening), and related material supply and cost. These are all important factors that one needs to consider before and during assay development. As a reference, many of these considerations have been described in detail in a document made publicly available through the National Institutes of Health (NIH) Chemical Genomics initiative (http://www.ncgc.nih.gov/guidance/manual_toc.html).

### 3.1 Biological Relevance and Validation of Assay Pharmacology

The importance of the biological relevance of an assay used in screening cannot be overemphasized. The scientist developing an assay for HTS should investigate the details of the biological system before attempting to develop an assay for screening. Neglect or reluctance to put time upfront to study the biology and pharmacological aspects can sometimes lead to a catastrophic failure of an HTS campaign. When studying the biological system of the target, one should specifically consider some of the following:

- Target "drug-ability": What evidence is there to support the hypothesis that this target is amenable to modulation by small molecules, that is, "drugable"? Does the target belong to an enzyme or receptor class that has historically been a preferred drug target class or is this a completely novel target class based on new evidence?
- What is already known about the system or target itself? What are the properties of the target or the reaction involved (if the target is an enzyme)? What are the preferred binding partner(s) or substrate(s)? Which isoform or splice variant is more relevant? What are the specificity and selectivity issues? Are there any kinetic and stability issues? One needs also to consider the mode of inhibition (or activation) of interest, and biosafety concerns of running the assay as a HTS, and the like.
- What are the biologically relevant conditions and the environment of the biological system/target? These include buffer, pH, ionic strength, cofactor requirements, substrate concentrations, and other effectors.
- Will the proposed assay reflect the system being interrogated? What could be the biological and

experimental artifacts of the assay? What biological or pharmacologic experiments can be performed to validate the assay? Even factors such as the order of the reagent addition and reaction initiation can make a significant impact in regard to physiological relevance.

- Importantly, what are the alternatives for the primary screening assay? These alternatives need to be considered in selecting the primary assay for the HTS campaign.
- What would be the counterscreens and orthogonal assays to confirm the hits? In addition, secondary assays usually will be needed to further validate or classify the hits from the primary screen.

One typical example regarding biological relevance is the ATP concentration used in in vitro kinase assays. The physiological cellular concentration of ATP is in the low millimolar range. If the inhibitor of interest is non-ATP competitive, the ATP level can be set at a concentration close to the physiological concentration. On the other hand, if ATP competitive inhibitors or both ATP-competitive and noncompetitive inhibitors are sought, then a much lower concentration (at or below the $K_m$) of ATP should be used. Another example is from inhibitor screening for some blood coagulation factors. A desirable inhibitor should have the advantageous trait of fast inhibition kinetics, in addition to the potency and other preferred pharmacological profiles. Therefore, in this case, there is no need to preincubate the target enzyme with the test compounds before introducing the substrate.

### 3.2 Assay Format Selection and Development Considerations

Beyond the consideration of biological relevance, an assay for HTS has other requirements and considerations. Preferred HTS assays not only require robust signal, high throughput, and small assay volume, but also require adequate sensitivity, accuracy, and reproducibility in order to be able to discriminate among a very large number of compounds that span the entire range of activity. An improperly designed HTS assay may fail to detect the desired classes of hits even if it is trivial to execute.

***Assay Format Selection*** As illustrated in the previous section, there are two major assay types in HTS, biochemical and cell-based assays (Fig. 3). The selection of assay format should be driven by the need to develop a readout with high sensitivity, reliability, and biological predictiveness. For speed, ease of use, and reduction in data variability, assay procedures with as few steps as possible are preferred. It is desirable to use the lowest possible biological target concentration in an assay. Not only will this save reagent, but also the assay will be sensitive and will be able to discriminative among the most potent hits in an activity series. Of course, one has to strike a balance between assay sensitivity versus signal strength (or signal robustness), which will affect the reliability of the measurements and the overall data quality. For any specific target, there are usually several assay formats available to choose, from isolated in vitro biochemical assays to cell-based assays, and from heterogeneous formats to homogeneous formats. All being equal, homogeneous assays are preferred over heterogeneous assays, and nonradioactive assays are preferred over radioactive assays. Some homogeneous assays such as TR-FRET (HTRF), FP, AlphaScreen, SPA, and chemiluminescence (e.g., HitHunter cAMP detection) are popular formats in HTS for both in vitro assays and cell-based assays. For cell-based assays, several common assay formats are reporter genes (luciferase, etc.), FLIPR, Cytoblot, and high-content imaging. Some newer assay formats based on label-free detection (waveguide sensing, cell electronic impedance, LC/MS) emerge as newly preferred assay formats.

***Assay Optimization*** Some general considerations in assay development and optimization are given here. For biochemical binding assays, the dissociation constant ($K_d$) and maximum binding ($B_{\max}$) should be known or determined. Specific binding versus nonspecific binding will determine the specific assay signal strength, data reliability, and quality. Any nonspecific signal should be keep as low as possible, and the specific signal should be minimally several-fold larger than that of the nonspecific signal. Characterization of the binding kinetics (rate constants $k_{\text{on}}$, $k_{\text{off}}$) is also important for equilibrium or nonequilibrium binding behavior. Ligand binding as a function of receptor concentration should be in the linear or pseudolinear range.

For enzymatic assays, several excellent reviews [82, 83] detail the strategies and tactics used during assay development. The principles of enzymology are always a useful guide during assay development [84]. Briefly, an enzyme titration should be conducted to determine the minimum enzyme concentration that can be used, the $K_m$ values of substrates, and the turnover rate; all of these should also be assessed to ensure the linearity of the reaction kinetics. These parameters must be determined experimentally. For HTS assays, many researchers prefer a linear time window of 30–120 min to facilitate plate handling and throughput, while kinetic readings can also be implemented for some fast reactions. As will be discussed, the pharmacology of reference compounds should be used to validate the assay. The substrate con-

centration is preferably chosen to be at or below the $K_m$ value to ensure a sensitive and linear signal response. Sometimes, in order to ensure measurement accuracy and to generate a robust signal, substrate concentrations [S] at two or three times the $K_m$ is a common compromise. To exclude competitive inhibitors, the substrate can be set at $[S] > 10K_m$, or at as high a concentration as the substrate solubility permits, for example, using millimolar concentration of ATP in screening for non-ATP competitive inhibitors.

When an assay signal is very weak under conditions that still lie in the linear range of substrate titration, either substrate concentration or conversion of the substrate need to be increased to enhance the signal-to-background ratio. It is generally accepted that the conversion of product should be kept at <10% of the total substrate used when studying enzyme kinetics. When the substrate is poorly soluble, the researcher is left with only one choice, that is, performing the assay at >10% product conversion in order to enhance the robustness of the assay (as monitored using the $Z'$ factor, which will be discussed later). However, at >10% conversion, the observed inhibition will be influenced. Wu et al. [85] have described the relationship between the half-maximal inhibitory concentration ($IC_{50}$) value for a given inhibitor and the percentage of substrate conversion using a first-order kinetic model under conditions that obey Henri–Michaelis–Menten kinetics. The study concluded that the $IC_{50}$ and percent inhibition values are only slightly shifted to less potent values even with much higher substrate conversion (up to ~40% conversion to product). This analysis provides a sound rationale for using higher substrate-to-product conversion as a compromise in optimizing an enzymatic assay for the needs for robust signal and sensitivity to inhibitors.

Other components in the reaction buffer also play important roles in assay optimization. Cofactors or prosthetic groups of the enzyme, cationic or anionic ions, pH, detergents, carrier proteins, and so forth all need to be tested during assay development and optimization. In many cases, the optimization can be performed by varying one or two relevant factors at a time. Sometimes it may be more efficient to use the design of experiment (DOE) approach to vary more factors simultaneously [86]. Regardless of the use of the one-at-a-time optimization approach or the DOE optimization approach, preknowledge of the factors pertinent to assay signal is extremely useful. However, it should be noted that buffer optimization is only an intermediate step; once the final buffer conditions have been defined, the assay must be again checked to assure that appropriate reaction kinetics are occurring.

Assay development of cell-based assays offers a stark contrast to that of mechanism-based biochemical assays. There are many discussions in the literature and review articles on the pros and cons of cell-based assay versus biochemical assays. We do not intend to reiterate those here [87, 88]. The fundamental considerations in cell-based assay design are similar: that the signal is specific and linear with the ligand and cell number (or protein/receptor level within the cell). The cell/receptor and time response linearity are key in assay optimization. Sensitivity, robustness of the signal, and reliability of the reading are important assay quality indicators. False positives and false negatives due to other cellular events (toxicity, expression instability, etc.) are more important issues to be taken into account. For example, the use of dual luciferase reporters (e.g., firefly and Renilla luciferases) can discriminate real inhibition from cell toxicity and product instability. Even with such normalization, the correct interpretation of the signal can be confounded by nonspecific effects on the reporter gene promoter or on cell proliferation [89].

***Assay Pharmacological Validation*** Whenever possible, the assay system under development needs to be validated by some appropriate biological or pharmacological test. There are a number of ways to accomplish this. Typical validation experiments include the use of some known reference inhibitors, the nonlabeled substrate as a competitor to the labeled one, or some known active and inactive effectors, as appropriate. If some known inhibitors are used, the pharmacological profiles (potency and efficacy) should be the same or very similar to those previously reported. Usually, $IC_{50}$ values, or better yet, $K_i$ values within three-fold from well-documented values are usually acceptable in HTS assays when performed under the same or very similar conditions. The rank order of potency of some known activators/inhibitors should also be identical or at least very similar to the reported potency rank order [90]. For instance, in the development of a particular kinase assay, if known compounds such as staurosporine have been tested in other laboratories or reported previously for the enzyme, the HTS assay should yield similar or comparable results to assure the assay performance and its hit finding capability. This should be true in both biochemical and cell-based assay development. Assay quality assessment and statistical validation will be discussed in the next section.

### 3.3 Assay Data Quality and Statistical Validation

In most HTS programs, each compound is only evaluated in a single test during primary screening. A high degree of accuracy and sensitivity in the assay is therefore critical for identifying active compounds (or "hits"). Due to various unavoidable sources of error or

variability, the measurements from any assay will contain a certain degree of variability. Yet hits need to be identified in the presence of such variations in signal measurement. Reducing the measurement variation will provide higher fidelity to the screening data. Therefore, in the design and validation of HTS assays, assessment of the screening data variability, by metrics such as the standard deviation (SD) and coefficient of variation (CV) of the replicate data set, is critical in determining whether an assay can identify hits with high confidence.

***Z′ Factor in Screening Assay Quality Assessment*** The quality of an assay can be loosely expressed as signal-to-noise (S/N) ratio and/or signal-to-background (S/B) ratio. Both ratios reflect the assay signal strength and therefore are useful parameters in assay quality assessment. In HTS, compound activity is normally expressed as a percentage measured against some selected reference control signals, usually a high reference control and a low reference control. However, both S/N and S/B ratios fail to take into account information from data variability of the sample and reference controls, as well as the assay dynamic range at the same time. To overcome some of the pitfalls of S/N or S/B ratios, Zhang et al. [91] proposed a simple statistic, the *Z* factor (*Z′* factor) as defined below, for use in evaluation of assay performance and assay signal robustness in HTS.

The data quality of an assay can be estimated by the *Z′*-factor formula:

$$Z' = 1 - \frac{3\sigma_{c+} + 3\sigma_{c-}}{|\mu_{c+} - \mu_{c-}|}$$

where ($\sigma_{c+}$) and ($\sigma_{c-}$) are the standard deviations for data from the high reference controls and low reference controls, respectively, and $|\mu_{c+} - \mu_{c-}|$ is the absolute value of the difference of the two control signal means. The *Z′* factor defines the *usable* dynamic range (usually the linear range) of the assay. Thus, the *Z′* factor contains data variability information of both the high and low reference controls (the same high and low reference controls usually used for normalization of the measured raw data to a percentage activity) as well as the dynamic range information. Therefore, compared to CV, S/B, or S/N, the *Z′* factor is more appropriate for evaluating overall assay quality. It is a useful tool for the evaluation, comparison, and validation of any assays, in general, and has been widely used for quality control (QC) of HTS assay quality and suitability.

As originally proposed, *Z* factor refers to the specific *Z′* factor when the mean and standard deviation of one of the corresponding reference controls are replaced by those of the testing samples. Therefore, *Z* factor reflects the test sample in screening and *Z′* factor is for the assay. *Z* factor has been used as a screening quality assurance parameter for assay plates owing to its sensitivity toward signal strength and data variability of test samples on the plate as well as the hit rates on the plate. *Z* factor is also affected by the screening conditions such as the compound concentration.

Generally, a *Z′*-factor value of close to 1 is an ideal assay for HTS, $1 > Z' > 0.5$ is considered a good-quality assay; $0.5 > Z' > 0$ can be a moderate to a poor-quality assay; and assays with $Z' < 0$ cannot really be used in HTS. These provide, however, only a rough categorization of assay quality for HTS and should not be regarded as absolute rules. Also, this metric applies to single-point screening. When multiple (*n*) repeat measurements of a test sample are obtained in a screening, standard error (SE) should be used instead of standard deviation; therefore, assay quality can be improved accordingly by square root of *n*.

There are several limitations in using the *Z′*-factor statistics in HTS. First, *Z′* factor should be assessed using large data sets, and both high and low reference control signals should approximate a normal distribution. In some rare cases where either the data distributions deviate severely from normal distribution or ($\sigma_{c+}$) and ($\sigma_{c-}$) values are hugely different, the *Z′*-factor values can become less effective or even meaningless for indicating the assay data quality. Another limitation is that, due to its dependence on two reference control states of the assay, the *Z′* factor becomes a less defined measure of assay quality for stimulator or agonist screens if there are no known stimulator/agonist reference controls available. When a strong or natural agonist/stimulator is known, then the *Z′* factor can be rightfully defined.

***Other Assay Data Quality Indicators*** Besides the commonly used *Z′* factor, and S/B and S/N ratios, there are a few other assay performance statistical parameters used in the HTS literature. A "signal window" (SW) ratio had been reported to evaluate the performance of HTS assays [92]. The so-called assay variation ratio (AVR) was also used to evaluate assay quality [93]. AVR and *Z′* factor are interrelated and interchangeable with one another, except that the originally recommended values for the acceptable and unacceptable assay for screening were somewhat discrepant. Iversen et al. [94] conducted a simulation study and compared the performance of *Z′* factor with SW or AVR, and recommended *Z′* factor as a preferred assay performance measure. Many assay developers use *Z′* factor in conjunction with CV, S/B, or S/N to give a more comprehensive assessment of the assay variation and performance.

Several groups of researchers have also advocated the use of power analysis as an assay quality indicator

[95, 96]. While this approach is certainly statistically sound, it should be noted that power analysis is usually based on one reference state of the assay signal distribution, and, therefore, whether it will reflect the overall data quality of the assay over the entire dynamic range is an open question. Compared to power analysis, $Z'$ factor is a much simpler statistical parameter to use and can be used routinely during a screening campaign to track the assays quality.

***Detection Sensitivity of an Assay*** As with measures of HTS assay quality, there is more than one way to assess assay sensitivity. First, the assay sensitivity can be evaluated by the lower limit of detection (LLD) of the assay measurement. The LLD as assay sensitivity limits are evaluated in terms of the S/N ratio. The S/N ratio is a good indicator for strength of signal. An analyte concentration giving an S/N = 3 is conventionally regarded as the LLD of the assay measurement with regard to that analyte. Similarly, one can use an analyte concentration that gives $Z' = (-1)$ as LLD of the assay [91]. In HTS, an assay sensitivity can also be evaluated by the limit of hit potency detectable with the assay. For example, when seeking inhibitors of a particular enzyme, what is the potency limit of inhibitors that likely will be detected by the enzyme inhibition assay when screened at a certain compound concentration? In assessing the sensitivity of an assay with regard to detectable compound potency, Buxser and Vroegop [95] used Michaelis–Menten kinetics and Langmuir binding isotherms, combined with fundamental statistical principles, to deduce a measure of assay sensitivity for inhibitors. This approach takes into account the compound screening concentration, the data variability of the assay, the $K_m$ or $K_d$ of the reaction, and the substrate or ligand concentration used. Then, the threshold or cut-off values used for determining "hits" and their probabilities of being detected by the assay can be evaluated.

***Data Repeatability and Reproducibility*** Another aspect of HTS quality is data repeatability and reproducibility. Here, repeatability refers to the ability of the same assay to be "cloned" and run in multiple copies with identical or similar results in one experiment at one time. Reproducibility describes the same assay run at a different time or in different laboratories. Since each HTS campaign is a considerably large effort and most screens are only performed in a single test, the assay data repeatability and reproducibility thus become an important part of the assay validation process. Traditionally, and in our labs routinely, after the assay has been developed and optimized, several replicates of assay plates containing high and low reference controls or other selected known reference compounds are tested with the HTS instrumentation. The means (or medians) and standard deviations of the high and low reference data sets are calculated. Then, the corresponding CV, S/B, and $Z'$ factor are obtained from these test results. These data uniformity tests may be repeated (reproduced) at different times with independently prepared reagents. The same sets of statistical parameters are obtained and compared. The data from these rigorous uniformity tests give more reliable evaluation of assay data quality ($Z'$, CV, S/B, etc.) than from the tests performed at the bench-top with fewer data replicates.

In addition to assay quality, plate data uniformity, and reproducibility assessment, it is a good idea to run some further validation tests before the real large-scale screening starts. These include blinded tests for some known reference compound controls, or a small-scale pilot (initial) screening. In a blinded test, the known reference compounds (e.g., known inhibitors) are spiked randomly into some wells on the assay plates in several dosing levels or in a titration series. These blinded testing and initial screening results can be used to further assure the assay's hit-finding capability and reliability.

### 3.4 HTS Compatibility

A distinct difference between a general bioassay and an assay for use in HTS is that the latter must be suitable for a high-throughput process. Many assays which routinely produce acceptable or good results with reliable quality at the bench-top scale may not be suitable for HTS simply because the throughput is too low or too complex and cumbersome for automation; or the assay may simply be too costly for large-scale screening. Therefore, compared to a general bioassay, an HTS assay has more requirements and constraints. These requirements include throughput, ease of running and automation, cost-effectiveness, and the availability of a reliable reagent supply. These properties can be collectively referred to as the assay's HTS compatibility. One popular assay type is homogeneous (also called "mix and read") assay as it only involves liquid addition, some incubation period, and then reading of the signal directly. Many types of assays can be configured in a homogeneous assay format, while others may need to adopt heterogeneous formats, as described previously in Section 2.

## 4 SCREEN DESIGN, PROCESS, AND INSTRUMENTATION

If one addresses the assay biological relevance, assay quality, and HTS compatibility and feasibility, there

should not be any major hurdles at the screening implementation and execution stage. Execution of a successful HTS campaign needs careful planning and process optimization to ensure that the data generated from the screening is reliable and consistently of good quality. Conceptually, the HTS implementation has several phases as described below.

### 4.1 Screening Design and Logistics

No matter whether the assay is a biochemical or cell-based assay, after successful development and validation of the assay, the next task is to implement it for HTS. The HTS process can be quite different depending on assay type and facility. Specifically, the HTS implementation will be influenced by assay protocol, resources (personnel and instrument) availability, type of instruments and capacity, library size, and the means for data capture and data flow logistics. The HTS will also be influenced by other process issues such as scheduling (time and space), reagent supply, waste, project time line, and costs. A screening process flowchart with detailed assay protocol and instrumentation will always be helpful in designing and planning logistics for the process. For example, the assay type will usually affect the screening design and process profoundly. For homogeneous biochemical assays, the screen is usually simple to design and implement. For heterogeneous assays, more washing or separation steps may need to be accounted for. The instrumentation required for carrying out the specific assay must be carefully chosen and calibrated, and the whole process must be carefully validated. Furthermore, if the assay is to use a radioactive material or other potentially hazardous reagents, operational safety and waste management issues have to be worked out according to regulations.

***Plate Format and Plate Type*** Perhaps the major difference between the current HTS process and the low-throughout screening processes used before the arrival of HTS is the use of standardized microtiter plates or multiwell plates. The use of standardized microplates has not only enabled many different assays to be performed at high density and speed, but they have helped to standardize HTS instruments (liquid dispensers, detectors, etc.). The result of this standardization of instruments is that they can be used interchangeably or in a combined manner. A standard 96-well plate contains an $8 \times 12$ array of wells each typically capable of holding a volume of 200–300 μL. A 384-well microplate contains a $16 \times 24$ array of wells each typically being able to hold a maximal volume of ~120 μL. Low-volume 384-well plates have been developed that can hold volumes of ~25 μL per well. With the development of low-volume liquid handlers and readers, higher density plates such as 1536-well plates ($32 \times 48$ well array, assay volume 5–10 μL) are increasingly being used. Reagent savings in these low-volume microplate formats are substantial, besides the enhanced throughput due to reductions in plate manipulations.

Sporadically, other assays using plate formats such as 864-, 3456-, and even 9600-well plates have been reported [97]. These formats have not gained much popularity, presumably due to the lack of compatible liquid handlers and readers, as well as the associated difficulty of compound reformatting. The need for assay miniaturization is driven by needs for increasing throughput and reducing reagent usage and cost [98]. Other non-plate-based screening formats have been reported, but so far, they have not gained as wide acceptance in the screening community (for a review, see [99]). Beyond compound screening, some assay chip technologies are now used in genomic and gene expression screening. With the advances of screening technologies, such as noncontact picoliter dispensers, liquid spotters, and MS-based or imaging-based detectors, a convergence of compound and genetic screening formats and methodologies appears possible in the near future.

The majority of the microplates used in HTS are made of either polystyrene or polypropylene. Most 384- and 96-well plates are available with well shapes of circular, squared, or squared with rounded corners and in conical, flat, and round well bottoms. Clear, white, or opaque plates for well walls or bottoms are available for different detection purposes. Plates can be pretreated or coated with special materials for specific use, such as plates treated for cell culture, high/low protein binding, or FlashPlate for in-plate scintillation detection. Some of the new technologies in multiplexing, label-free detection, and acoustic energy based liquid transfer requires special plates with requirements such as protein-arrayed bottom, electrocircuited bottom, optical sensing bottom, and cyclic olefin copolymer (COC) plates for compatibility to the corresponding technologies.

***Plate Layout*** The positioning of test samples and reference control wells on the assay plate can be quite flexible and is dependent on the experimenter and affected by liquid handling process. From a statistical point of view, the controls and test samples should be placed in such a way that systematic errors can be minimized. Usually, statisticians suggest a "mixed" or randomized layout to minimize systematic errors. This would help to avoid systematic errors that can occur when controls are placed along a column, usually at one edge of the plate. Such a nonrandom layout may over-

estimate or underestimate the control mean if there is an edge effect of the assay on the plate.

In practice, however, there are several constraints in selection of the position and layout of the samples and controls. The mostly encountered constraint on the layout of the assay plate is that imposed by the layout of the compound storage plate, with the only flexibility available in the placing of the high and low reference controls in certain columns or rows. For example, in some common layouts, columns 23 and 24 of a 384-well plate may be the only 2 columns available for placing controls. Alternatively, columns 12 and 24 may be available for the controls. But there are still many possible ways of placing high/low controls and other reference/standards in these control columns. Several routinely used layouts are either one column for high control and another for low controls or half of a column for high and half for low controls in both columns. The selection of the control layout is often dictated by the convenience with which liquid handlers can add the high/low controls into the reference wells.

Another approach that has been taken by some laboratories is to eliminate control wells on each plate and instead to have a few "control plates" added at regular intervals between assay plates throughout a screening run. Such an approach has the advantage that systematic effects on the plates (such as center or edge effects) can be more easily detected. Yet other laboratories may choose to use plate median as the "inactive controls," given the majority of the compounds on the assay plate being inactive.

### 4.2 Instrumentation and Automation

***Instrumentation for Liquid Handling and Signal Detection*** The demand for higher throughput has driven the advancement of HTS instrumentation and also higher density microplates. Some of the earlier instruments for multichannel liquid handling in HTS labs were automated or semiautomated systems and workstations from Zymark, TomTeck, Beckman Coulter, Tecan, Robocon (CRS), CyBio, Matrix, TiterTek, for example. In recent years, many more advanced systems have become available, most notably from Perkin-Elmer, Velocity 11, Thermo Electron, and so forth, in addition to the aforementioned vendors. Meanwhile, several new picoliter to nanoliter liquid dispensing technologies have matured and are being increasingly used in HTS. Examples are noncontact liquid dispensing devices such as acoustic dispensing devices.

Many new signal detection methodologies and instrumentation have also become available in recent years, ranging from general multifunctional fluorescent and optical detectors to highly specialized plate readers (e.g., MesoScale) and instruments for high-content imaging (such as ArrayScan-II, In-Cell 3000, etc.). Label-free detection has shown much promise for new screening paradigms. Some examples are LC/MS-based screening, surface sensors, and cellular dielectric impedance changes. As long as the pressure for increasing drug discovery productivity continues, the use of advanced instrumentation and automation will continue to increase in HTS laboratories.

***Workstation versus Fully Integrated Systems*** Every HTS laboratory is designed based on its role within the drug discovery process and the organization it serves. The challenge for each screening laboratory is to balance the required throughput against expenditure, complexity, and the changing needs of their organization. As mentioned above, a wide range of microplate-based liquid handling and signal detection equipment are available in the marketplace. Some laboratories use full robotically controlled systems while others utilize standalone workstations. Each of these approaches for screening has its advantages and pitfalls.

Workstation mode has the clear advantages of simplicity, flexibility, low cost, and easy setup. In a modular workstation-based HTS lab, screens usually require microplates to be processed through several different instruments, each of which is programmed to perform a single task. Each instrument module functions independently from other modules and can be interconnected using simple robotic arms. Liquid handlers and readers are usually equipped with plate stackers or simple robotic arms. For instance, compound plates preparation, assay reagent dispensing, washing, and signal detection are carried out separately according to the assay protocol. However, with this process people have to be involved with executing each separate task in a screen. Human errors are therefore more likely to arise. Plates are usually processed in batch mode, sometimes leading to more pronounced batch-to-batch variation. The throughput of workstation screening is limited by the working hours of the people involved. With innovation on ultra-HTS and miniaturization, throughput issues are being addressed, and specialized workstations or semiautomated setups may be suitable options.

Modern fully integrated screening systems allow rapid processing of screening plates continuously throughout the day in an operator-independent or nearly independent manner. Even with fully integrated systems, operators are still required to "feed the machine" and to remove its waste as well as review and analyze the screening results it produces. Key elements of a typical fully integrated robotic screening system

include a working platform, plate-handling robotics (arm robots, cylindrical coordinate robots, or overhead Gantry robots) with intelligent plate gripers, linear servotrack, controller, the integrated barcode scanners, liquid-handling units (dispensers, aspirators, washing station, plate centrifuge, mixers/shakers), incubators, plate storage units for compound source plates, and/or assay plates. A software operating system with programming capabilities for scheduling of different tasks, error detection, warning, and fault rectification is also an indispensable component of the system. Some of the large HTS systems integrate online data analysis/visualization to allow quality control and database interfacing. The demand for increasing throughput requires that these systems perform reliably and can accommodate a variety of screening assays with less failures.

For fully integrated robotic systems, the major advantages includes alleviating people from tedious labor and repetitive work, allowing them to conduct "higher level" intellectual tasks. The robotic system can work for long hours with less human involvement. The data generated from a screen is generally in a strictly controlled manner and therefore usually more uniform in quality. The major disadvantage of fully integrated robotic systems are the long design and implementation times required, and the overall and upfront costs of fully automated screening systems relative to the workstation-based setups. In addition, there are additional costs associated with hiring specialist engineers for troubleshooting, maintenance, operating, and training others. These additional support labors (and costs) for fully automated robotic systems can offset the labor savings for screening personnel. Another disadvantage is that often more stringent biological reagent stability is required for implementing an assay on a fully automated system [100], potentiating the inflexibility of the systems. Sometimes it takes a longer time for troubleshooting and optimizing an assay on such a system than the real productive screening time on the robot.

Arguably, subjective matters such as different philosophies on managing HTS largely determine the instrumentation setup and thus affect the screening process design. In many cases, the sight of many robotic arms moving in a laboratory gives a strong visual impression of productivity and frequently creates inflated expectations in throughput [101]. The true challenge and measure of success of a robotic screening system, besides expense evaluation, is the time spent on productive use in generating quality data versus the time spent on repairing broken parts and retooling the system to accommodate the diverse application needs in HTS. Again, the best system may be flexible use of people and machines, depending on the diversity of the task and the screening needs.

### 4.3 Screening Process and Quality Control

***Pilot and Primary Screening*** The screening process involves several steps such as pilot run, primary screening, primary hit confirmation and validation ($IC_{50}$ determination and counterscreen), and associated data analysis. The first stage in the screening process is usually an initial, or pilot, screen. During a pilot screen, a subset of compound plates, for example, a small randomly selected compound plate set, a preselected diversity set, or a specific set of test compounds, such as the LOPAC set from Sigma-Aldrich, are used, and the assay plates are processed through the entire screening process, using the same liquid-handling and detection instrumentation and data-handling and analysis systems. The primary goal of such pilot screens is to validate the anticipated screening process. The pilot screen is useful not only in revealing some of the logistic issues the process may encounter, and so allow tuning of the process, but also in evaluating the test compound concentration, allowing an estimate of the hit rate for the full screening. Pilot screens also provide the first set of data to go through the data processing and analysis work flow. If everything looks normal or as expected, the full-fledged HTS campaign starts.

Regardless of whether the screen is performed with workstations or with a fully automated system, procedures should be kept consistent throughout the entire screening campaign. Additionally, as data is generated during the primary screening, it should be constantly monitored with suitable quality control measures. If problems arise during the screen, it will be necessary to pause the process for troubleshooting, before screening is resumed. Quality control and data analysis of screening results will be described and discussed in the following sections.

***Screening Quality Control (QC)*** In modern drug discovery, screening is an industrial-scale process used to survey hundreds of thousands to millions of compounds on selected biological targets. As described above, the process is dependent on a suitable bioassay with sophisticated instrumentation, automation, and various detection technologies. Many factors beyond the biology of the assay influence the quality and outcome of the screening. Thus, quality control is an integral part of the process, used to ensure good-quality data generated from screening.

Various statistical QC methods have been used in HTS. QC can be performed in an online or offline manner, depending on the setup of the HTS data acqui-

sition system. For workstation-based screening processes, QC is most likely carried out offline. For integrated HTS systems, on the other hand, if equipped with automated online QC software, a variety of readily interpretable graphs and tables of key QC parameters allow the operator to visualize HTS data quality and examine assay performance during the HTS process and to react to quality problems in a timely manner [102]. In most cases, QC in HTS is often focused on a limited set of control parameters such as S/B, S/N, $Z'$ factor, and $Z$ factor. Sometimes, more sophisticated QC analyses are used to reveal any systematic errors, patterns, and distribution deviations [103–107].

***Impact of Assay Technology Selection and Screening Efficiency*** It is fundamentally and pragmatically important to determine if a similar collection of active compounds are identified from the same chemical library using different assay technologies. Currently, there are usually many choices of assay formats available for various types of targets when developing an HTS assay. Results from several recent studies reveal that different assay and detection technologies can generate significantly different hit lists for the same biochemical interaction [19, 108–110]. For example, Wu et al. [19] have evaluated the same biochemical assay in a typical HTS setting with two different detection technologies. The results showed that the selection of assay technologies can make a significant difference in the screening results. However, there are other examples where the screening results, using different technologies, have been shown to be quite similar [111, 112]. The selection of assay detection technologies deserves careful justification and validation to maximize the hit-finding probability.

The issue of missing truly active compounds and collecting false positives from noisy screening data pose a serious problem for many HTS programs. Studies have begun to assess the intrinsic fidelity of primary screening results. Several approaches have been attempted to address this issue, from statistic models [113–115] to real case studies [116]. Usually, typical screens with reasonable activity cutoffs for selecting actives should have hit confirmation rates of 50% or above, and rates in the range of 60–80% are frequently seen. The hit confirmation, false-positive, and false-negative rates from a primary screen are mainly affected by (a) the HTS assay quality, (b) the hit limit selection, and (c) the chemical library used. Among these parameters, assay quality plays the primary role in determining the hit confirmation rate. However, since screening is a multistep process and errors can rise at any step in the process, many factors beyond the biology of the assay influence the quality and outcome of the screening process [105, 106].

### 4.4 Strategies of Compound Screening and Compound Handling

***Singleton versus Mixture Screening*** Compound samples, in most HTS campaigns, are only tested in singleton (each test well contains only one compound) at a single concentration. Synthetic compounds are usually created as single pure compounds by medicinal chemistry laboratories. However, some compounds, often originating from combinatorial synthesis, for example, split-and-pool synthesis, are only available as compound mixtures. In the latter case, active wells containing the compound mixture need to be deconvoluted in order to identify the actual active compound. In a similar manner, many natural product samples are only tested as crude extracts or semipurified fractions derived from different microorganisms or biological sources. Again, in this case samples identified as active by screening need to be further purified and analyzed to identify the active chemical structures. Natural products, as isolated and purified samples, can be treated the same way as pure synthetic compounds. The follow-up study of natural product hits is often more complicated and lengthy than for synthetic compounds. Nonetheless, natural products have proven to be valuable sources for active drug candidates for immunosuppressives, cholesterol-reducing agents, anticancer drugs, and antibiotics. In fact, most of the antibiotics currently being developed in the United States have been derived from natural products [117].

It is also worth mentioning one of the "old" strategies that has been applied to HTS: the strategy of compound matrix pooling [118, 119]. In this compound compression strategy, compound plates are pooled in orthogonal matrices (both horizontally and vertically pooled) across a small set of plates as mixtures, for example, mixture of 10 compounds. The result is that each compound is present twice in the pooled library, in two different mixtures. Therefore, compounds are tested essentially in duplicate, but the overall throughput still increases fivefold in the case of 10 compounds per mixture compared to testing single compounds. The primary hits can then be deduced by a self-deconvolution process, comparing the compounds present in the two different active samples. As long as the primary screening hit rate is not very high (e.g., <1%) and the assay signal is sufficiently robust, this strategy seems to work well. A recent comparison of this matrix pooling strategy with the singleton screening method yielded good concordance and comparability in hit finding [120]. This strategy was also used successfully in large-scale LC/MS-based functional screening to enhance throughput [34]. In other assay formats, particularly in affinity-based screening, larger compound mixtures of several

hundreds of compounds or more have been used [48, 50]. Some disadvantages commonly raised for mixture strategies are that compound mixing may show the so-called bystander effect (biological activity of the mixture may be affected by some compound interactions or interferences in the mixture) and that it may not work well for cell-based assays due to higher risk of compound interference and toxicity from the pooled mixtures. Therefore, this strategy is usually not recommended for cell-based assays. However, to our knowledge there is no published data to support or refute this assumption.

***Multiple Testing and Other Screening Strategies*** In addition to screening in singleton or mixtures, other compound screening strategies have been used in various situations. For example, when an assay quality is not sufficiently high, and the assay reagent and throughput are not limiting factors, the screening can be performed in duplicate to enhance hit-finding probability. Another common strategy is to use a two-tier hit selection in primary screening and hit confirmation/validation. Both strategies can be efficient in reducing false hits when applied appropriately. Some of the pros and cons of these approaches have been discussed previously [116].

When reagent supply and screening capacity is not a constraint, one can directly test each compound in multiple doses to eliminate the potential problems of data uncertainty with a single-dose test in routine screening campaigns. Inglese et al. [121] have recently reported a multidose compound screening approach, and called it "quantitative HTS" (qHTS). A similar strategy has been also used for some time by the National Cancer Institute (NCI) screening group [122]. A dose–response curve and $IC_{50}$ values can be directly deduced for each compound screened. This approach has the potential to reduce false-positive or false-negative hits. However, despite these advantages, it is still not clear if this approach is worthwhile in most cases, particularly when the hit rate is low, as is typical for a random compound library screen.

***Counterscreen*** All assay detection methods will generate some artifacts due to interference from compounds, resulting in false-positive hits in the primary hit lists. Different assay readouts have a tendency to generate different artifacts. Counterscreens have to be designed and used to eliminate most of those detection artifacts and nonspecific hits from the primary biological assay. For example, in a luciferase-based reporter gene assay, an inhibitor can either inhibit the specific activation of interest or reduce the signal by nonspecifically killing the cell, or even simply by inhibiting luciferase enzymatic activity. In this case, a counterscreen can be configured by employing a constitutively activated luciferase in the same parental cell line to weed out the toxic and nonspecific inhibitors (i.e., false positives) of the assay. An alternative strategy might be to use a different reporter gene with a different readout of activity, for example, β-lactamase activity or a dual luciferase system. It is noteworthy that a counterscreen in this sense is different from other orthogonal, secondary assays or a selectivity test for further characterization of the hits. A counterscreen may have slightly different meaning in different laboratories. It is also highly recommended to run orthogonal assays to further confirm the hits, given these assay technologies are well-validated themselves.

***Compound Diversity*** The selection of the compounds to be tested during a screening campaign is one of the most important determinants for the success of HTS, regardless of whether it is for a large diversity-based or an information-based (focused) compound library. Even when there is no prior knowledge about a target to guide compound selection, there is still a need to select the appropriate compounds for general screening. There has been much debate, but little real data, concerning the question of how best to design libraries for exploratory screening. One school of thought contends that libraries should be as diverse as possible, including as many molecular features as possible [123]. Others have suggested "informative libraries," where the compounds included in the test set are chosen because they allow the testing of concepts of how a compound may interact with a target [124]. Yet others have suggested that just blindly screening a random selection of compounds is just as appropriate a strategy as any other selection method in finding novel structures [125].

The discussion on the appropriate choice of compounds to test has been greatly influenced by the work of Lipinski and co-workers who retrospectively looked at molecular and chemical-physical properties of drug molecules and their effect on oral availability [126]. This work lead to the Lipinski "rule of five" as a general rule that is widely being used by chemists in the design of "druglike" small molecules for drug discovery. This ground-breaking work has lead to other researchers looking at additional molecular features, for example, number of rotatable bonds, as additional guides to compound selection and design. This concept of druglike molecules has been taken further by Proudfoot [127] with his retrospective analysis of lead to drug compounds, which showed that, often during the lead optimization process, compounds increase in molecular weight and lipophilicity, leading to the concept that screening libraries should not be druglike but rather

leadlike. This approach has been taken further in the context of fragment-based screening strategies and has lead to the "rule of three," which has been combined with the concepts of the ligand-binding efficiency in compound design [128].

***Sublibrary Screening (Focused and Small Diverse Libraries)*** Lead identification by high-throughput screening of large, randomly selected compound libraries is supplemented with strategies utilizing virtual and focused screening approaches. Such approaches attempt to reduce the number of compounds tested and thus to increase the efficiency of screening, by using information already known about the target or the compounds that interact with it. This is in contrast to the strategy of "screening everything," which is based on the assumption that testing large, random compound libraries is an efficient way of identifying novel leads. However, increasingly, there is already information about many of the targets being selected for drug discovery projects, making such rational strategies more attractive. Currently, there seems to be a trend toward the use of structure-based focused libraries [129–131]. Recent advances in high-throughput computational docking, nuclear magnetic resonance (NMR), and crystallography also have facilitated the application of focused library screening. For example, focused libraries have been used to help generate hits or lead compounds for kinases and other targets [132–135]. The focused libraries can be populated by either high-throughput cherrypicking or by combinatorial or focused synthesis [136, 137].

Generally, the scaffold diversity of a focused library is relatively low. Therefore, medium or small sized diverse sublibraries, designed using structural diversity and drug-likeness measures, is another approach for the rapid and efficient discovery of hits or leads [138]. As mentioned previously, the analysis of diversity is complex and subjective and has been a source of controversy [125, 139]. Whether a focused, screening strategy or screening a diverse compound library will do a better job in meeting both the scientific standards and business needs of discovering novel drugs remains to be seen, but it is an active area of current research in drug discovery.

***Fragment-Based Screening*** Fragment-based screening is a lead discovery approach in which lower molecular weight (120–250 Da) compounds than those usually present in the chemical libraries are tested in HTS campaigns. The number of compounds in fragment-based screening libraries are often significantly smaller than those used for HTS, and therefore the library design is even more important [140]. Even though these compound libraries are smaller, they are able to more efficiently sample available chemistry space with many of its possible combinations [141]. Further consideration to optimize the chemical tractability of the fragments present in generic fragment libraries have been included in library design strategies [142].

Compared with hits from HTS, the hits from fragment-based screening approaches usually have much lower affinity for their target (10 $\mu M$ to millimolars). As a consequence, compounds tested in fragment-based screens need to be present at higher testing concentrations and assayed using biophysical detection techniques such as NMR or crystallography rather than bioassays. However, hits from fragment-based screening methods typically possess high "ligand efficiency" (binding affinity per heavy atom) and so are highly suitable for optimization into lead candidates with good druglike properties [143]. However, it should be noted that these strategies do not lead to the identification of a unique solution to the identify and locations where the fragments that can bind, with fragmentlike compounds being able to interact in multiple ways at a particular proteinligand binding site. The consequence is that fragment-based screening could lead to the development of multiple leads [144].

***Compound Management and Integrity Characterization*** Chemical libraries routinely used for screening may contain large numbers of compounds, usually from hundreds of thousands up to one million or more. The increasing size of the compound collections used for screening has created a need for specialized hardware and software for automated compound management in order to cope with the increasing demands in HTS, as reviewed by Chan and Hueso-Rodriguez [145].

Compounds are usually stored as dry powders, in separate vials for each batch of compound synthesized, for long-term storage. Preparation of the compounds in a soluble form can be thought of as the initial step in the HTS. The preparation of compound solutions involves retrieving compounds from the compound store, distributing into microtubes, solubilization in dimethyl sulfoxide (DMSO), transferring and registration of the dissolved compounds into microplates (mother plate set), replica plating of multiple copies to intermediate plates (daughter plate sets), and then finally copying from these daughter plates into assay plates either with or without further dilution. These preparation steps are usually processed in a centralized compound management core facility. All of these different copies of compound plates and samples on the plates are registered with their attendant information being kept in electronic data files. Information

management systems are used to access and track the samples and link them to a variety of pertinent information that can help interpret HTS data.

Compound sample integrity and concentration accuracy should be monitored by appropriate QC procedures. Sample integrity and concentration accuracy in turn is linked to the quality and correct interpretation of the data generated from an HTS campaign. Various methodologies have been used for compound monitoring and characterization. Compound identity has been analyzed by LC/MS, NMR, and purity by LC/MS and ultraviolet (UV) spectrometry, evaporative light scattering, and nitrogen content [146]. Compound solubility and aggregation have been detected by light-scattering techniques, such as with a nephelometer. It has been proposed that "promiscuous inhibitors," possibly caused by colloidal precipitation, could be identified by enzymatic assays such as β-lactamase or chymotrypsin [147, 148]. Recently, a QC filter based on three 1D-proton NMR experiments has been proposed for rapid characterization of the identity, purity, solubility, and aggregation state of the active compound, for identifying false negatives and for detecting promiscuous inhibitors [149].

The commonly used compound solvent DMSO is hygroscopic and quickly absorbs water from the open atmosphere. Water presented in DMSO compound solutions can accelerate degradation and precipitation of some compounds. Understanding DMSO hydration in an HTS compound library can improve storage and preserve compound integrity [150]. A nondestructive, acoustic method compatible with HTS has been reported recently to measure water content in DMSO solutions. The performance of this acoustic method was compared with an optical technique and was reportedly in good agreement [151].

## 5 DATA HANDLING AND ANALYSIS

The relational database plays an essential role in an HTS laboratory. An integrated database enables compound registration, compound tracking, inventory control, assay/project registration, plate registration, version control, loading and storage of captured data from analytical instruments, data reduction/analysis/validation, and finally data mining for SAR or cross-target analysis. Figure 4 is a schematic overview of an HTS data management system.

This section focuses on the general data flow and aspects of HTS data analysis and data mining, which are the ultimate results of the HTS process.

### 5.1 HTS Data Analysis

***Data Flow*** A typical flowchart of HTS data analysis is shown in Figure 5. Data files captured directly from plate readers are first transferred to the bioassay data-

**Figure 4** Overview of an HTS data management system.

**Figure 5** Typical HTS data flow.

base and the data analysis system, where the data can be reformatted and linked uniquely with the compound sample identification number and other chemical information. These results reside in the system as raw data files. The raw data can be visualized, inspected, and checked with an appropriate set of quality control criteria. The plate data that passes these initial quality control filters is normalized by the designated reference values, usually by the mean positive and negative control signals. The normalized data can also be visualized, inspected, and checked again with a new set of more stringent quality control parameters. Systematic errors and other patterns detected by the analysis algorithm can be cautiously corrected if deemed appropriate. Finally, the resultant transformed data is ready for hit selection based on either statistical or activity criteria. The selected primary hits are subject to hit triage, data mining, or direct confirmation/validation testing.

***Data Normalization and Correction*** In most cases, the raw data is normalized platewise, using the mean signals from the positive and negative control wells present on each assay plate. In other cases, the positive and negative control wells may not reside on the same assay plate. It may be located on a QC plate that was run side by side with the assay plates during the same experimental run. Sometimes, rather than use the positive or negative control wells, the plate median signal is preferred to replace the corresponding control signal [107]. The argument for using plate median is that the control wells may not be representative of the sample wells, particularly when the control wells are not generated and treated exactly the same way as the rest of test samples. Depending on the specific assay configuration, one normalization method may produce slightly better results than the other. Generally, if there are no significant systematic errors or bias for the sample and control wells, these normalization methods should yield very similar results.

Data QC measures can be applied at several levels from wellwise to platewise to batchwise or even over an entire screening data set. If some systematic errors or patterns are detected, data analysis programs may apply a mathematic correction algorithm to compensate for the erroneous pattern in the data points (see [152] for a recent review) . It should be noted that any such correction should be cautiously justified before applying. As in any other scientific experiment, unless the systematic error and data pattern have a traceable, or at least an explainable cause, blind application of any correction can be very risky and is not recommended. Even if the systematic errors or patterns can be explained, as little data correction as possible should be applied, usually not exceeding 25–30% of the average signal in the screening data, as a rule of thumb. Any potentially problematic plates or data points flagged by QC parameters should be looked into carefully and retested if possible.

Visualization tools are indispensable parts of the data analysis system. One scatter plot display or a distribution histogram may offer more information about the quality of the screening or revealing potential issues than any data tables or statistical parameters. Some of the recommended visualization plots of HTS data were reviewed recently [152].

***Hit Limit Selection, Hit Rate, False Positives, and False Negatives in HTS*** Where is the best place to set the hit limit cutoff during primary screening of a chemical library? There is no straightforward answer. From a statistical point of view, it does not make a lot of sense if the hit limit setting is $<2 \times$ SD (standard deviations or modified equivalents) away from the activity mean of a random library. In many real screening campaigns, hit limits chosen at around $3 \times$ SD or greater or activity potency values (e.g., percent inhibition or stimulation) are used as the hit limit cutoffs. Since the hit limit is directly linked to primary hit rate, this means that in practice the chosen hit criteria is related to finding a

manageable number of compounds for hit validation and follow-up tests.

Since error is associated with any assay and screening process, the primary hits from a HTS will not be confirmed entirely. As mentioned earlier in this chapter, the hit confirmation rate, false-positive rate, and false-negative rate from a primary screen is influenced by not only the HTS assay quality but is also affected by hit limit selection and the primary hit profile from the screening library, as well as screening process and screening strategies. Several approaches have been used to assess false-positive and false-negative rates, from statistic models to real case studies [113, 114, 116, 153].

***Hit Confirmation and Validation/Dose–Response Curve Analysis*** The data analysis flow for hit confirmation testing is very similar to that of primary screening data. In a hit confirmation test, the hits are retested multiple times (e.g., 2–3 replicates) with the same assay used in the primary screen. The data for hit validation with dose–response analysis is normalized in a manner similar to primary screening results before curve fitting. The only difference in the treatment of the data is in applying any data correction. It is more difficult to detect and correct for any systematic errors and patterns on plates containing many dose–response tests. For this reason, separate set of control plates need to be tested along with the sample plates. The systematic errors or patterns found in the control plates are used for correction with sample plates. It can be very risky to apply such corrections and great care has to be exercised in doing so.

Dose–response curve analysis is usually carried out with common curve-fitting equations and programs. For most dose–response curves, a four-parameter, nonlinear equation is used for the curve fitting. Many kinds of competent curve-fitting software are readily available. Some of the challenging tasks for these analysis tools are outlier detection, curve-fitting model selection, and curve-fitting quality control. Visualization of the dose–response data with a fitted curve is an indispensable part of such analysis. Fully automatic curve-fitting algorithms that can satisfactorily fit curves to both inhibition and stimulation results are highly desirable.

### 5.2 Data Archive and Data Mining

Computational chemistry and cheminformatics have played important roles in successful HTS in the drug discovery setting. Several reviews have already summarized the use and impact of data mining on the discovery of compounds from high-throughput screens (e.g., [154–156]). There are a number of ways in which data mining can be performed to further improve the quality and analysis of HTS results.

***Chemotype Analysis and Hit Triage/Prioritization*** Cheminfomatics can make significant contributions to the screening process in at least several stages. First, cheminformatics has a significant impact on the compounds chosen for chemical library design. Library design can be as simple as removing unwanted compounds from the screening collection, such as removing reactive compounds or those containing moieties not believed to be of value to drug discovery (such as heavy-metal ion complexes; for a review see Rishton [157]). Another stage where cheminformatics impacts HTS outcome is when the primary hit list is evaluated to choose compounds for further validation and characterization. This hit triage process is needed especially in the cases where HTS campaigns identify more hits than those that can be practically progressed through validation and characterization.

Hit triaging can be considered as a series of steps:

1. The hits are filtered to remove those with reactive or "frequent hitter" characteristics. Cross-assay analysis and utilization of counterscreen data can reveal frequent hitters and nonspecific hits due to mechanisms other than the specific interaction on the target of interest.
2. The list usually is filtered again to remove compounds that are already known or known to be working by some inappropriate mechanism.
3. Apply appropriate "hitlike" or "leadlike" filters.
4. Cheminformatics then has the possibility to enrich the hit list by focusing on classes of compounds that are most likely to show reproducible activity using methods based either on modeling or clustering.
5. It can also ensure that a set of compounds with maximal diversity are selected for validation so that no one chemotype dominates the hit compound list.

***Modeling to Identify False Positives and Negatives*** High-throughput screening inherently carries the risk of generating false negatives as well as false positives. Significant effort has been invested in new technologies to help identify and deprioritize hits that are acting due to assay artifacts (false positives). However, other than independently retesting samples in a screen, there is little technology that can help to minimize false negatives. Data mining offers an alternative route for assessing and rescuing false negatives. A number of approaches have been proposed to use primary screening data to

generate models for predicting the activity of compound samples. Such models are then used to predict the activity of individual compounds so that the hits missed by screening can be rescued. A number of different model building methods have been applied in this way, including logistic regression [158], clustering [159], Bayesian modeling [160] and other sophisticated modeling methods. It has recently been shown that the greater amount of data offered by primary screening data can allow the derivation of models as predictive as models derived using validated $IC_{50}$ results [161]. Such methods also find application in genetic screens of small inhibitory RNAs (siRNAs) [162] and the evaluation of gene chip expression profiling [163]. All of these methods in a sense make the assumption that, by "averaging" the activity of compounds containing certain structural features (e.g., characteristics or substructures depending on the type of compound descriptors used), the potential activity of a compound can be predicted. However, a consequence of using such models is that "singleton" hits will be deprioritized for selection and hit follow-up, and therefore a balance in the application of such methods is needed. In addition, singleton false negatives cannot be rescued with such methods.

***Prediction of Mechanism and Off-Target Effects*** The modeling and mining of HTS data is not limited in use to identify active hits. Recently, such methods have been used to attempt to predict the possible mechanism of action of compounds, especially in cell-based assays where interaction with multiple targets may bring about the observed biological effect [164, 165]. As with approaches to predict activity against a single target, these attempts to predict the mechanism of action of a compound relies on clustering and Bayesian modeling methods. Essentially, these methods first create multiple models predicting the activity of compounds against a specific target or target class. Then, these models are used to predict the possible activity of any given compound in these multiple models; the models in which the compound is predicted to be active then suggest possible targets against which the molecule may be acting. Such methods also have been used to identify and explain the activity of compounds identified as frequent hitters in reporter gene assays [166] and so may be a way to help identify hits most suitable for lead optimization.

## 6 EMERGING TRENDS

Earlier sections have briefly reviewed and discussed the importance and different phases and aspects of the screening process from assay development and validation, design of the screen, quality control, data analysis, and the utilization of the HTS information to identify viable drug lead molecules. This section highlights several emerging trends that may play more important roles in the fields of HTS in early drug discovery, including fundamental approaches, technical advancements, and ongoing research interests in the HTS fields.

Currently, HTS capacity and throughput is often not perceived as a limiting factor in lead discovery. As a consequence, screening campaigns are no longer regarded as just an effort to screen as many compounds as possible (the "numbers" approach). The large number of "hits" generated from HTS campaigns in past years is slowly but surely starting to have a significant impact on the compounds coming to the clinic [167]. On the other hand, the "smart screening" approach of testing focused or designed sublibraries overall has also been of only limited success. How to construct the most effectively diverse or target-specific sublibraries is sometimes not even agreed upon by computational or medicinal chemists themselves. Thus, HTS is and will remain an important tool in early drug leads discovery for the foreseeable future, particularly for targets where little or no prior information is available or in cases where the goal of the project is to identify truly novel classes of inhibitors or ligands.

### 6.1 New HTS Approaches

HTS is facing new challenges and needs to adopt new approaches in order to improve efficiency and predictability to contribute to the early lead identification and drug discovery processes.

- ***Quality of HTS Assays Continually Improves*** This includes the continued development of new, high-quality assays that have better hit-finding capabilities due to improvements in biological relevance, reliability, sensitivity, and specificity. One of such approaches is the use of more direct readouts, such as MS-based assays. Another approach is the use of multiplexed readouts or well-validated orthogonal readouts, to enhance the efficiency of identifying "true" hits with desired activity profiles.
- ***Improvements in Screening Libraries*** The quality of the chemical library being tested has been shown to be at least as important as assay quality for a successful HTS campaign. The selection of a screening library with druglike and leadlike structures is a critical endeavor. The features of druglike and leadlike structures continues to be better defined. In addition, the diversity of druglike and leadlike molecular space continues to be explored

and categorized. The "preferred" or "privileged" structural scaffolds should be better characterized and, more importantly, better applied effectively in drug discovery and screening. Other areas of development will focus on the discovery and design of small molecules suitable for modulating protein–protein interactions and possibly a greater focus on natural productlike compounds.

- ***Combination of Potency Screening with Early ADME/Tox Testing*** The hits from potency-based screens should be evaluated, as early as possible, with a set of profiling (or selectivity) assays and toxicology testing. Such characterization will allow rapid triaging and filtering of HTS hits and, thus, maximize the chance of focusing on the chemotypes that may be more predictable and have lower attrition rates in the later stages of development.
- ***Combining and Exploring Novel Screening Strategies*** This may include evaluating strategies such as iterative screening in combination with strategies using lead modeling. Such iterative and combined screening strategies may reduce the apparent throughput and efficiency of screening (in terms of compounds screened per day) but may lead, overall, a more effective hit-to-lead discovery process. Similarly, HTS combined with other information-based screening strategies (various virtual screening and structure-based model building) will hopefully enhance the efficiency of hit expansion and evaluation. Therefore, HTS labs should also have medium throughput capability for screening higher value compounds in complex formats.
- ***Applying HTS in New Target Areas*** The needs of drug discovery will continue to drive the need for screening to be applied to new biological systems in order to support current drug discovery efforts. Some of the areas for which we see great potential for improvements for HTS is the development of additional assay formats for high-throughput ion channel readouts. High-throughput screening is a tool and an approach that has not just been limited to use in drug discovery but has also been applied in fields as diverse as genomic and proteomic discoveries, protein engineering, and the selection of chemical catalysts. Thus, it seems likely that the range of applications in which HTS is applied will continue to grow with increasing awareness of the power of this strategy.
- ***Increase in Academia Outreach and Collaboration*** HTS is no longer limited to industrial setting and is starting to play an increasingly important role in academic research [26, 168, 169]. With the new NIH initiatives to support a number of screening centers in the Molecular Libraries Screening Center Network (MLSCN) (http://nihroadmap.nih.gov/) for academic research use, it can be expected that the mutual impact of HTS and basic biology will increase, as well as the collaborative efforts in hit finding and target identification between academia and the pharmaceutical industry.

### 6.2 New Technologies

It is no doubt that new enabling tools will be important for future biomolecular screening. During the last decade, HTS has seen a paradigm shift enabled by advances in miniaturization, liquid handling, new assays, and improved detection technologies. Looking into the future, several trends emerge.

***Assay Miniaturization*** The pressures of cost constraints and throughput will continue to drive the need for assay miniaturization. Plate-based assay technologies will continue to be the dominant assay format. Non-plate-screening technologies have been developed and used at times in the past and will make increasingly more impact in future years. It is also possible that microfluidic assays and chip-based assay technologies will drive the miniaturization of HTS assays into new dimensions.

***Noncontact Liquid Handling*** With the continued drive for assay miniaturization, noncontact liquid-handling devices will play an increasingly important role. Currently, liquids are most conveniently handled by pipette tips for aspiration and dispensing into microtiter plates. Noncontact dispensing has been also used, such as Multidrop, FlexDrop, solenoid, and piezoelectic microdispensers. Recently, with the acoustic energy-driven liquid-dispensing devices (such as the ECHO550 or EDC system), liquid can be transferred in a small volume (nanoliter to microliter) accurately and directly from the wells on one plate into wells on another. So far, these devices have been best used for dispensing DMSO compound solutions, making it possible to run microliter volume assays without the need for tedious predilution steps. Increasing the speed and throughput of such transfer will further increase the number of assays that can be miniaturized. The transfer of aqueous solutions is also feasible with these devices. These nontip liquid transfer devices eliminate the need for tip washing and reduce the chance of liquid cross contamination.

***Label-Free Detection*** As mentioned above, the current signal detection methods in high-throughout

assays are predominantly fluorescent, colorimetric, or radioactive based. Such assay formats all require specifically labeled reagents and are subject to colored and fluorescent compound interference to various extents. In the last few years, new label-free detection systems based on surface sensors for in vitro and cell-based assays as a new detection paradigm in the HTS and related applications emerge [53]. A common requirement in these label-free detections is that the target or substrate have to be immobilized on a specialized surface for detection, with the exception of MS-based detection. One major advantage of MS-based functional screening is that it is not only label free, but it is a direct readout without any need of target or substrate immobilization. MS has been shown to be a powerful tool in HTS and has been used both in affinity-based screens and in functional-based HTS. Therefore, MS-based detection is a more generic detection method than many other label-free methods. Besides LC/MS-based HTS, other desorption-based MS detection technologies are also in development for use in HTS.

***High Content and Multiplexed Readouts*** Another emerging trend in HTS detection is multiplexed readouts. The traditional screening assay only monitors one or two signals of the testing system. With some specialized assay detection technologies, multiple readouts can be obtained. For example, a multimodule detector can simultaneously detect fluorescence intensity, fluorescent lifetime, and FP or FRET signals. Analysis of multiplexed readouts can provide information to discriminate a hit as either a true inhibitor or as an artifact caused by some interference with one of the detection modes. In a similar vein, high-content imaging analysis-based screening (HCS) also provides multiple readouts depicting cellular changes. With appropriate image analysis algorithms, a combination of the most relevant parameters, often deduced after unbiased analysis of all the possible readouts using tools such as principal component analysis, can be used to better assess the action of each hit and to eliminate false-positive hits. One of the challenges in multiplexed readouts or high-content imaging is the development of high-throughput methods to perform data analysis on more than a dozen different measurements with vastly different ranges of activity and activity distributions.

Another important set of assays with multiplexed readouts are assays to monitor messenger RNA (mRNA) transcript levels. The expression level of all the genes involved in a known signal transduction pathway or relevant selective genes can be monitored simultaneously as a way of monitoring the most relevant effects of a compound on a cell. The current technologies for multiple mRNA detection include quantitative reverse transcriptional polymerase chain reaction (PCR) (qRT-PCR), quantitative nuclease protection assay (qNPA), and Massarray assay technologies. The applications of such multiplexed in vitro and cell-based detection systems should provide more predicative information in hit and lead finding.

In summary, we reviewed the HTS processes and related methods and strategies in the above sections. HTS has become an indispensable tool for drug lead identification and discovery across the pharmaceutical industry. As a discovery tool, HTS still needs much improvement to be more efficient and predictive. In the foreseeable future, HTS will remain a fast growing field not only in pharmaceuticals but also in academic research with broader applications.

## ACKNOWLEDGMENTS

We would like to thank Dr. S. Siehler for help describing the reporter gene assay technologies, Dr. Q. Lu for help describing the ion channel assays, and Dr. M. E. Digan for help proofreading the manuscript.

# MASS SPECTROMETRY

Robert D. English and Anthony M. Haag
*University of Texas Medical Branch, Mass Spectrometry Core Laboratory, Biomolecular Resource Facility, Galveston, Texas*

## 1 INTRODUCTION

The intent of this chapter is to provide a concise summary of informative topics related to the study of therapeutic agents by mass spectrometry (MS). Due to the vast number of published studies in this field alone, we have elected to restrict the cited literature to only the most recent as possible. Our objective is to highlight as many pertinent MS techniques as possible. However, it should be noted that this will not be an all-inclusive list of approaches due to the large volume of literature. Additionally, our intent is not to emphasize equations and detail about theory; a plethora of textbooks, training manuals, and journal articles concerning these details already exists. Theory will be discussed and referenced in this work only when its integration can make points more understandable.

This chapter is primarily divided into the areas of instrumentation, sample preparation, and applications in proteomics, metabolomics, and emerging fields in drug analysis. Each division will be discussed using examples from recent literature with the expectation that the reader will navigate to the appropriate topic for explanations and for direction to relevant citations. More time will be spent on instrumentation details in the first part in order to build a solid platform on which to discuss relevant applications in the latter portion of this review. Moreover, specific mass spectrometer designs used in the development and analysis of therapeutic agents will be given more attention based on their relevance and abundance in the literature.

## 2 INSTRUMENTATION

### 2.1 Sample Purification

In general, most MS experiments are easiest and results most accurate when a sample is as homogeneous as possible. Otherwise, the interpretation of mass spectra becomes less trivial, for example, when dealing with multiple-charge peaks in an electrospray ionization (ESI) experiment. Although software for deconvoluting ESI mass spectra accompanies most if not all commercial mass spectrometers nowadays, the software is usually unable to determine sample purity. The software attempts to identify the most probable protein(s) based on mass spectral comparison between experimental and theoretical data.

There are numerous methods employed in the fractionation, desalting, and specific selection (binding) of sample components prior to analysis and detection by MS. We will discuss several forms of sample treatment that make the analysis of pharmaceuticals and related drugs possible by MS.

***High-Performance Liquid Chromatography*** High-performance liquid chromatography (HPLC), also known as high-pressure liquid chromatography, is the most widely used (online) method of sample separation for analysis by MS. HPLC is so commonly used that, at the time of this writing in July 2011 when we executed a Scifinder Scholar [1] search (criteria: *dates 2003–2011, journal only, English language*), almost 95,000 hits were

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

registered. When the search was restricted to "HPLC and MS" using the same criteria, the list was decreased to 9901 hits. Further restriction of the search terms to "HPLC and MS and drugs" resulted in 6354 hits, "*containing all of the concepts*".

Choice of chromatographic separation depends on the relevant application. HPLC practice and theory is readily available [2, 3]; however, some common HPLC separation methods include reverse phase, normal phase, ion exchange, and size exclusion. HPLC typically uses pressures up to approximately 6000 psi in order to maintain a constant flow rate of approximately 1 mL/min; keeping a stable flow rate enables reproducible chromatography conditions. The stationary phase is packed into a column that must be physically capable of withstanding these high pressures. Reverse-phase (RP) chromatography is by far the most common means of separation used today both with and without MS. The separation mechanism relies on different solubilities in buffered aqueous and organic solvents. C18 (and C8) are the most common hydrocarbon-based alkyl groups bonded to the inner 5- or 10-μm porous silica surface. The linked carbon-based alkyl group is the bound, *nonpolar* surface on which analyte adsorption occurs. This nonpolar stationary phase allows for the most polar compound to elute first from the column; the opposite holds true in *normal-phase* chromatography where a stationary polar phase dictates that the least polar component is eluted first. More detailed information can be found about HPLC stationary phases in the literature [4].

Oftentimes a gradient elution profile for the mobile phase is used so that the ratio of organic solvent (such as acetonitrile in RP-HPLC) to water incrementally increases during the course of the chromatographic separation. As the various adsorbed compounds experience a changing organic content, the analytes of interest desorb and elute from the column based on their solubility with the mobile-phase composition. On the other hand, isocratic elution conditions can also be used, which leave the mobile-phase gradient unchanged.

Many commercial HPLC detectors are used in the detection of eluting compounds. Examples of these types of detectors include absorbance, fluorescence, light scattering, Fourier transform–infrared (FT-IR), electrochemical, refractive index, conductivity, and last, but certainly not least, mass spectrometry [5]. As a stand-alone technique, ultraviolet (UV) absorbance is the most widely used detection method of choice. A review article was recently published that, in part, surveys approximately 40 examples of HPLC assays for analyzing bulk pharmaceuticals and formulated drug products [6].

In order to take full advantage of HPLC, however, chromatography should be coupled to a stand-alone or post-UV detector mass spectrometer. Linking HPLC to MS combines the separation power of HPLC with the sensitivity of MS [7]. Both techniques can stand alone but are much more effective when coupled together as an LC/MS instrument, as evident by its increased attention and usage in research articles, commercial instrumentation, and work flows in pharmaceutical companies over the past two decades [8–10].

Without HPLC, identification of compounds in a mixture is sometimes possible but is certainly less trivial. Utilizing HPLC to allow "pure" components to be injected into the mass spectrometer takes full advantage of the sensitivity of MS because mass spectra of countless compounds are specific enough to allow identification with almost complete certainty, thereby making identification of numerous components in a mixture much more likely. Specific LC/MS examples will be addressed in more detail in later sections.

***Nanoflow HPLC*** Nanoflow refers to HPLC under much slower mobile-phase flow rates in the nanoliter/minute rather than the microliter/minute–milliliter/minute flow rate as in conventional HPLC. Instruments using nanoflow HPLC are becoming more widespread [11–16]. It must be mentioned, however, that there are several advantages as well as disadvantages to working in the nanoflow regime.

The disadvantages of nanoflow HPLC make it problematic under certain conditions. First, quantitation is very difficult due to spray instabilities into the mass spectrometer at this low of a flow rate; this problem can be circumvented, however, through appropriate use of internal standards as performed by Applied Biosystems [17]. Second, irregular ion production may occur due to desolvation of small droplets occurring too rapidly. Third, additional hardware such as splitters must be utilized in order to decrease the flow rate from conventional HPLC pumps used in this setup; this problem is normally addressed by the LC manufacturer unless a custom-built system is being used.

The advantages of nanoflow HPLC make it a very popular technique. First, less sample is consumed and injected during this process. Only 1 μL of sample volume is often required for injection into the mobile phase, although it is a concentration-dependent process. Second, ionization efficiencies approach 100% in the mass spectrometer due to the fact that the droplets formed during ionization are thought to contain only a single analyte molecule; in other words, there is less ionization suppression within smaller droplet sizes. Third, ions can be produced from high water-containing mobile phases. Fourth, the slower flow rate allows this

nanotechnique to be married to other separation techniques such as capillary electrophoresis (CE).

***Ultraperformance Liquid Chromatography*** The theory behind ultraperformance liquid chromatography (UPLC) is not as new as its popularity. UPLC uses sub-2-μm particles and (higher) pressures up to approximately 14,000 psi in order to gain improvements in resolution, analysis time, and detection sensitivity [18–20]. Additionally, UPLC can result in shorter run times via LC/MS/MS (MS/MS is a tandem MS technique that allows for precursor ion selection and deliberate fragmentation to give structural and sequence information) analysis of small molecules and peptides. Increased resolving power and absolute quantitation were demonstrated with the analysis of a serum digest on an Applied Biosystems 4000 QTrap hybrid triple-quadrupole linear ion trap mass spectrometer [21]. The advantages of UPLC were realized by Mazzeo and co-workers when they applied it to metabolite identification and quantitation [18]. UPLC/MS/MS demonstrated faster analysis speed and higher sensitivity compared to HPLC/MS/MS. A problem with UPLC, however, lies in the fact that nonlinear effects are present at these high pressures; these effects create solvent compressibility issues not typically encountered in traditional HPLC.

***Pulsed Ultrafiltration*** Pulsed ultrafiltration (PUF) is typically used in combination with MS and combinatorial libraries to screen chemical mixtures for compounds that bind to specific receptors [22–24]. In a typical PUF-MS setup, a solution chamber contains a porous membrane for molecular weight selectivity. A pulse containing an extract or a library of compounds is passed through the chamber where both ligand–receptor complexes and unbound components form. Following a wash cycle to eliminate the unbound compounds, the bound ligands are eluted into an HPLC column and then injected in their desalted forms into a mass spectrometer for analysis and identification.

Compared to other affinity-based techniques, PUF has advantages and disadvantages. Native conformations and binding interactions of ligands and receptors, respectively, are conserved because the reaction occurs in solution phase. Also, receptor compounds can be recovered and reused in a PUF experiment. Moreover, PUF can be used online with MS when volatile buffers are used, a scheme not common to all techniques. A disadvantage of PUF is that one needs to minimize nonspecific binding of molecules to the inner chamber surface and membrane.

A similar technique to PUF is ultrafiltration-MS, which uses centrifugal ultrafiltration as opposed to a membrane to separate bound and unbound complexes [25].

***Frontal-Affinity Chromatography*** Frontal-affinity chromatography (FAC) is based on the principle that compounds are in a dynamic equilibrium with an immobilized target (on a column) [26]. The unbound compounds are eluted earlier than the bound, with subsequent analysis by MS. FAC is used in many studies including protein–ligand characterization such as protein–protein, protein–drug, protein–small molecule, protein–DNA (deoxyribonucleic acid), and even protein–carbohydrate interactions. Additionally, FAC can be found in ligand discovery studies [27, 28]. In one study, the binding properties of inhibitors of the epidermal growth factor receptor were analyzed, and an approach was developed for quick screening of drug candidates from natural resources [28].

***Other Sample Purification Methods*** A recent review article describes many more affinity-based MS screening methods [22]. In it are discussed affinity size exclusion–MS [29], affinity capillary electrophoresis–MS [30], surface plasmon resonance–MS [31], affinity capture–MS [32], and noncovalent affinity–MS [33]. All of the techniques use MS as the final identification step of binding ligands, however, the approaches do slightly differ in the principle of separation of binding compounds from unbound components. Affinity size exclusion–MS uses fractionation in a spin column to achieve separation of target-ligand complexes. Affinity capillary electrophoresis–MS measures the mobility change of ligands upon reaction with target to identify bound ligands. Surface plasmon resonance, or SPR-MS, identifies the binders for an immobilized target by measuring the change in surface refractive index. Affinity capture–MS identifies bound ligands by mixing a bead-bound target with potential ligands. Noncovalent affinity–MS is the only affinity-based MS sample purification method that measures the mass of a ligand-target(s) complex by analyzing the target-ligand mixture directly with no prior separation or washing of bound and unbound compounds.

***Desalting*** Ionic compounds are often required to keep many biochemical samples stable in a buffered environment; however, they can hinder ionization in the mass spectrometer and/or cause the formation of adducts with the sample. This would not be a problem if it did not in turn decrease or inhibit the ionization for the protonated form of the analyte, which is most often the case. Many desalting approaches are used, some of which include ziptips, dialysis, spin columns, and desalting columns.

Ziptips (manufactured by Sigma) are a fast, simple, and effective method for cleaning up samples requiring routine matrix-assisted laser desorption/ionization (MALDI) and ESI mass spectrometric analysis. Ziptips are readily available with C4 or C18 nonpolar stationary phase bound to a resin in the end of a pipette tip. The desalting process takes only a few minutes and involves only a few solutions to concentrate a sample for subsequent mass analysis. Most often, acetonitrile is used to wet the resin. Next, 0.1% trifluoroacetic acid (TFA) is used to condition the tip. Then, the sample of interest is aspirated many times through the pipette tip in order to bind the sample to the resin. To wash the sample and remove salts, 0.1% TFA is used again. Finally, the sample is eluted from the resin with only a few microliters of a mixture of organic/water with a small amount of acid. The exact ratio of solvent composition varies depending on the peptides or proteins of interest because the process is based on sample-dependent, hydrophobic properties. A commonly used elution solvent in our laboratory is 50/50 or 70/30 acetonitrile/water in 0.1% TFA when using C18 ziptips.

Dialysis is a very cost-effective technique used both to separate differently sized molecules and to exchange a solute's solution (i.e., buffer exchange). Exchanging a nonvolatile buffer with a volatile buffer can be extremely beneficial for MS experiments because fewer problems are encountered with volatile buffers. In ESI, for example, nonvolatile buffers can clog the ionization tip in the mass spectrometer ionization source. Molecules are dialyzed by using size-selective, permeable tubing with high volumes of buffer washing. Some advantages include the low cost and reuse of the dialysis tubing, as well as that it is not a concentration-dependent technique. Disadvantages include long duration cycles and copious amounts of required washing.

Spin columns are a convenient means of desalting/purifying samples. They typically include some nonpolar, stationary phase (i.e., C18) for sample purification and subsequent concentration. For example, protein sample can simply be combined with a resin inside the column, and then the purified sample eluted following a washing step.

Desalting columns are another practical and easy approach for sample purification, and they function very similarly to spin columns. They are made out of a variety of materials with varying pore size so as to act as a molecular weight filter for the size of interest. These columns are commonly used for desalting large biomolecules such as proteins.

## 2.2 Ionization Sources

Information regarding many areas of mass spectrometry can be found in numerous analytical chemistry textbooks [5, 34], mass spectrometry textbooks [35–39], proteomics books [40], and Internet websites [41]. As of July 2011, a Google search of just the term "mass spectrometry" resulted in almost 11.6 million hits.

Before discussing any individual aspect of a mass spectrometer, it is useful to first briefly address the system as a whole. In simplest terms, mass spectrometers measure the mass-to-charge ($m/z$) ratio of a compound. The necessary components of any mass spectrometer include an ionization source, mass analyzer, and detector. Compounds must first be introduced into the mass spectrometer, whereupon they become: ionized and then accelerated by an electric and/or magnetic field; mass analyzed and separated according to their $m/z$ ratio; and detected at a device whereupon its signal is sent to and processed by a computer. If a gas-phase molecule cannot be ionized, then the compound is considered to be a neutral (zero charge), will not be affected by the field, and will not be detected.

An ionization source, the topic at hand, is vital to all mass spectrometers. Many ionization techniques are available, however, we will discuss four common types: electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), matrix-assisted laser desorption/ionization (MALDI), and atmospheric pressure photoionization (APPI).

***Electrospray Ionization*** The advent of ESI, one of many atmospheric pressure ionization sources, revolutionized the analysis of (large) biomolecules in the mid-1980s [42, 43]. Although techniques such as plasma desorption mass spectrometry (PDMS) [44], fast atom bombardment (FAB) [45], and secondary ion mass spectrometry (SIMS) [45–48] had been shown to desorb nonvolatile molecules, ESI became one of the most widely used ionization techniques after its inception because it produces gaseous ionized molecules from a liquid solution. In other words, ESI could easily be coupled to an HPLC system, which paved the way for new applications in biological research for mass spectrometry.

Briefly, desolvated ions form from charged liquid droplets. This process is realized by the creation of a spray of charged droplets in an electric field at a metal tip maintained at several thousand volts. Multiple-charge ions do commonly form during the ESI process. Although the mass analyzers on ESI instruments typically only pass molecules with $m/z$ values of 2000–3000, larger molecules (with molecular weights up to several hundred kilodaltons, but more routinely up to 70–100 kDa) can be analyzed because the ionization process can attach numerous protons, or charges, to molecules with sufficient sites, thereby pushing the $m/z$ of the compound(s) into the range of the mass analyzer.

ESI has many advantages. First, as previously mentioned, it encompasses a high practical mass range, primarily because of multiple-charge ions realizing the detection of macromolecules. Second, under the right conditions, it can be a highly sensitive technique (low picomole–femtomole). Third, ESI easily adapts to LC interfaces. Fourth, there is no matrix interference as with MALDI, meaning low-molecular-weight species (100–800 Da) are more easily identified. Fifth, ESI is a soft ionization technique that allows for the study of noncovalent interactions.

Disadvantages of ESI include low tolerance for mixtures (unless combined with LC), multiple charging (makes interpretation of spectra sometimes complex and in need of deconvolution software), and low salt tolerance.

***Atmospheric Pressure Chemical Ionization*** An atmospheric pressure chemical ionization (APCI) source is another ionization technique useful for a class of compounds sometimes not identified easily by ESI [49]. A corona discharge serves as the driving force behind forming and maintaining the ion-molecule reactions present in this plasma that ionize the neutral analyte molecules. Briefly, a corona discharge occurs when the field at the tip of an electrode ionizes the surrounding gas, where the vaporized solvent acts as the reagent gas. The analyte ions are subsequently transferred into the mass spectrometer in the same manner as with ESI; the interface between the ionization sources (APCI and ESI) and the mass analyzer is identical, the only difference being that APCI also requires a heated pneumatic nebulizer (along with a spray chamber and needle as in ESI) to be placed in front of the mass analyzer.

Some advantages of APCI (compared to ESI) include: low to slightly high polar compounds can be analyzed, higher LC flow rates (2 mL/min) can be used, and higher tolerance to buffers in the mobile phase can be tolerated.

APCI suffers from lower reproducibility, however, compared to other ionization techniques. Unlike desorption methods that can analyze nonvolatile species, APCI (and other atmospheric pressure ionization sources) requires that the analytes of interest be volatile. APCI does not function well at lower LC flow rates, and may contain more analyte–buffer adducts in mass spectra.

***Matrix-Assisted Laser Desorption/Ionization*** Matrix-assisted laser desorption/ionization (MALDI) [50–53] is yet another soft ionization technique but somewhat different from the aforementioned atmospheric methods. Briefly, a focused beam of light from a laser (UV, IR, or Nd:Yag) is directed onto a solid support containing a mixture of both analyte and matrix under vacuum. The sample/matrix is desorbed from the surface upon interaction with the pulsed light beam. Although the exact mechanisms of ion formation are still debatable today, the purpose of the matrix is threefold: to co-crystallize with the sample, to absorb at a similar wavelength or energy as the laser so as to only allow minimal or no fragmentation of the target molecule, and to donate or withdraw a proton from the sample in order to form the required sample ions needed for acceleration into a mass analyzer. Upon formation, ions (positive or negative charge) are accelerated into a mass analyzer [typically, a time-of-flight (TOF) field-free region] via an electric field. It is within the TOF region that ions separate according to their respective *m/z* ratio and are subsequently detected at the end of the drift tube at an ion detector. Reflectrons are often used in conjunction with the flight tube to bend the trajectory of the ions; this increases the length of the TOF region and corrects for different kinetic energies of ions with the same *m/z* ratio.

MALDI is advantageous for several reasons: practical mass range of several hundred kilodaltons, typical sensitivity in the low femtomole range, soft ionization with little fragmentation, and tolerance of millimolar concentrations of salt and other ionizing suppressing compounds. Disadvantages include matrix background (inhibits routine analysis of molecules less than 800 Da), photodegradation of sample by the laser desorption process, and cannot be connected to online HPLC.

***Atmospheric Pressure Photoionization*** Atmospheric pressure photoionization (APPI) is a newer ionization method compared to all methods described previously [54]. APPI is oftentimes used as an alternative to APCI. The primary difference from APCI is that rather than a corona discharge as the ionization vehicle, APPI utilizes a UV light source. APPI sometimes can ionize species not possible by APCI, just as APCI can ionize species sometimes not possible by ESI. All three techniques are often used in a complementary fashion because of both the advantages of each ionization source and the relative ease of interchanging the sources on the same instrument.

### 2.3 Analyzers

Mass analyzers are another one of the basic components to a mass spectrometer. After ionization occurs, the charged molecules must enter another region of the mass spectrometer in which separation of the ion mixture occurs. Nowadays, there are many mass analyzer designs and variations that accomplish this task. Some analyzers not only separate charged ions from each other but also store and filter the ions. In other words, one analyzer can function in several modes. This multifunctioning ability often makes it advantageous to

design mass spectrometers that utilize more than one type of analyzer in a single instrument. Mass analyzers measure the *m/z* ratio. This becomes especially important when compounds take on several charges (*z*) because the *m/z* will be much less than the actual mass (*m*) of the compound. Mass analyzers can directly affect instrument parameters such as resolution, mass accuracy, mass range, and overall sensitivity.

Many common types of analyzers include quadrupole, ion trap, magnetic sector, double focusing magnetic sector, time-of-flight, Fourier transform–ion cyclotron resonance, and numerous variations and combinations (i.e., hybrids) of these analyzers [55]. Several of these analyzers are discussed below.

***Quadrupole*** Quadrupole mass analyzers can be found in a plethora of instruments (such as triple-quadrupole mass spectrometers). In fact, triple-quad instruments have been the workhorse in pharmaceutical company laboratories and will continue to be widely utilized. A unique feature to the quadrupole analyzer is that several can be put in tandem within the same mass spectrometer in order to perform very specialized analyses involving both *m/z* and structural determination.

A typical quadrupole analyzer is also known as a mass filter because of its *m/z* selection capability. A direct current (DC) voltage and a superimposed radio-frequency (RF) potential is set across four parallel rods. The field across the poles dictates ion (*m/z*) transmission to the detector. Ions moving into the field inside the poles will oscillate based on their *m/z* values. Only ions of a specific *m/z* will pass through the filter given a particular RF potential, and only by scanning the RF field can a full mass spectrum be obtained. Quadrupoles (Q) can be used in tandem for MS/MS experiments to give not just *m/z* values but also much needed structural information. A specific *m/z* ion can be selected in Q1 and fragmented in Q2, and fragment (or product) ions can be scanned in Q3, for example. Q1, Q2, and Q3 are described in more detail in Section 2.4. Many hybrids using quadrupole analyzers are possible and will be addressed later.

***Ion Trap*** The behavior of ions inside an ion trap is very similar to that of a quadrupole analyzer. Ions can be stored, accumulated, and ejected from an ion trap to produce tandem MS data [56]. Tandem MS experiments can give the much sought-after molecular structural information. Because of its ability to conduct tandem MS experiments of complex mixtures of peptides (such as generated by trypsin digestion), the ion trap is perhaps the most common analyzer found in current mass spectrometers used for proteomics research. The linear ion trap (LIT) has been replacing many other ion storage analyzers because they have higher ion-trapping capacities to increase overall sensitivity, slower scanning functions to increase resolution, and $MS^n$ capabilities for structural elucidation.

***Quadrupole Ion Trap*** The first commercial quadrupole ion trap (QIT), a type of linear ion trap, was introduced in the early 1980s [57]. A QIT stores ions within a three-dimensional RF quadrupole field and has an *m/z* range of approximately 3000. The QIT consists of two endcaps and a ring electrode in replacement of one pair of conventional quadrupole rods. As in the other analyzers previously discussed, ions of a specific *m/z* (or *m/z* range) can be trapped by creating stable trajectories while simultaneously removing unwanted ions through the creation of unstable trajectories. The operation and fundamental concepts of the quadrupole ion trap are described elsewhere [34].

***Orbitrap*** The Orbitrap is patented technology by Thermo Electron Corporation (San Jose, CA) and is a newer analyzer that is capable of selection and storage of ions with a specific (or range) of *m/z* values through the separation of ions in an oscillating electric field. A schematic and details of the Orbitrap can be found elsewhere [58, 59]. A primary advantage to this analyzer over others is its mass accuracy and high-resolution capabilities that are beginning to rival those values conventionally only obtainable by Fourier transform–ion cyclotron resonance (FT-ICR), which requires the use of an expensive superconducting magnet.

***Time-of-Flight Analyzer*** The time-of-flight (TOF) analyzer became popular once again (on the heels of many successful years of the quadrupole analyzer in gas chromatography–mass spectrometry (GC-MS) instruments) after the introduction of MALDI, an ionization technique that produces pulsed packets of ions whose *m/z* analysis is very amenable to the TOF analyzer. A concise history of TOF analyzers can be found elsewhere [53]. Although Wiley and McLaren are the most popular for introducing a TOF mass spectrometer that addressed and improved the spatial and kinetic energy distributions on mass resolution [60], others too had either suggested and/or built TOF instruments [61–66].

In the most basic terms, the TOF analyzer is the simplest type of mass analyzer in mass spectrometry. The basic components necessary for a TOF-MS instrument include an ion source/extraction region, a drift region (tube) for separation of ions according to their velocity (proportional to their *m/z*), and a detector. Ion separation is based on their mass and velocity according to the kinetic energy equation. The lighter ions arrive at the detector sooner than the heavier ions because they have

higher velocities (the ions are given the same voltage, which directly translates to the same kinetic energy).

***Other Analzyers*** *FT-ICR* The Fourier transform–ion cyclotron resonance (FT-ICR) analyzer is becoming more commonplace in analytical laboratories ever since its introduction more than 30 years ago [67]. Commercial versions are now available from vendors such as Thermo Electron Corporation (San Jose, CA) and Bruker Daltronics (Billerica, MA). These instruments can be very costly. On the other hand, mass accuracies of 1–2 ppm and resolution greater than 100,000 are routine [68].

*Q-TOF* The TOF analyzer can often be found placed on the back end of a quadrupole (Q-TOF). The Q-TOF combines the mass selectivity of the quadruple with the resolution of the (nondisciminate mass selection) TOF analyzer. MS/MS data can be acquired with the Q-TOF instrument giving the much desired fragmentation (i.e., structural identification) of a compound.

*TOF/TOF* The TOF analyzer can often be found placed on the back end of another TOF (TOF/TOF) [69]. MS/MS data can be acquired via sequential steps. First, upon selection of a precursor ion that has been separated according to its *m/z* in the first TOF region (TOF1), subsequent fragmentation occurs in a collision-induced dissociation (CID) or postsource decay (PSD) region. In this region ions are decelerated, fragmented, and reaccelerated. These fragment ions are then analyzed in the second TOF region (TOF2) where they separate according to their *m/z*, pass through a reflectron, and impact a detector. The combination of MALDI with MS/MS capability has made the TOF/TOF a more powerful tool to the mass spectrometrist or proteomics researcher than ever before.

### 2.4 MS Scanning Acquisition Methods

There are a variety of modes in which to operate triple-quad mass spectrometers and hybrids such as the Q-Trap (quadrupole ion trap) as offered by Applied Biosystems (Foster City, CA) [70]. Oftentimes MALDI-based mass spectrometers are unable to confirm posttranslation modifications (PTMs) of compounds, and false-positive identifications are common as the number of PTMs increases (i.e., database size increases). Triple-quadrupole and hybrid versions, however, add a selectivity dimension because of the versatility of the analyzer(s). The array of scanning acquisition methods discussed herein are popular among the Q-Trap [70] and triple-quad mass spectrometers for targeted analysis [i.e., selected reaction monitoring (SRM) acquisition for PTM analysis] as such in the pharmaceutical and proteomics industries. Figure 1 lists many of these tandem MS modes along with pictorial descriptions concerning the ion behavior and selection within each quadrupole and/or ion trap [71].

***Q1, Q2, and Q3 Analyzers*** Q1 is the first quadrupole that ions will encounter. Typically, this quadrupole is used to scan all masses to yield a full mass spectrum. Q1 can also be used to select an ion of a specific *m/z* for further introduction into the second quadrupole, Q2, for CID. CID allows deliberate fragmentation of ions to study structures such as peptide sequence analysis and common moieties in pharmaceutical drugs and metabolites. Q3 is the third quadrupole and is used to scan the fragment ions resulting from the CID of a specific *m/z* ion in Q2, or it can be used to only analyze specified point masses from selected ion fragmentation pathways as input by the user.

A *Q1 scan* consists of a full scan using only the first quadrupole. Typically, the user sets a predetermined mass range, and a mass spectrum is produced of ion intensity verses *m/z* of all detected ions. A *Q1 multiple-ion scan* is a scan of only specified masses as input by the user. A *Q3* scan is analogous to the *Q1 scan* above, except that a full scan is performed using the third quadrupole Q3. A *Q3 multiple-ion scan* is similar to the *Q1 multiple-ion scan*, with the exception that the recorded mass spectrum is the result of a scan of the third quadrupole for specified masses.

***Precursor Ion*** Precursor ion scan mode is an MS/MS full scan in which Q1 sweeps a specified mass range, Q2 acts as a collision cell where precursor ions undergo fragmentation, and Q3 is fixed to only transmit one specific product ion to the detector. This can be used in many analyses when searching for an ion that generates a specific *m/z* fragment or product ion (e.g., functional group).

***Product Ion*** When searching for all the fragments or products of a specific precursor ion, a product ion scan (the most common tandem MS experiment) is implemented. This MS/MS scan involves fixing Q1 to only transmit a specific precursor ion. This chosen ion subsequently undergoes fragmentation in a collision cell (such as in Q2), and Q3 sweeps a mass range and analyzes the resulting product ions.

***Neutral Loss*** A neutral loss experiment is yet another tool to track an ion before and after the loss of a neutral group (i.e., phosphate group). This mode consists of both Q1 and Q3 sweeping a mass range with a fixed mass apart. Only an ion signal will be registered when

**Figure 1.** Schematic representation of various types of tandem MS experiments. (A) Product ion scanning generates fragment ion spectra for the identification of the amino acid sequence of specific peptides. (B) Precursor ion scanning is typically used to detect a subset of peptides in a sample that contains a specific functional group. (C) Neutral loss scanning also detects peptides that contain a specific functional group and is more often used in the detection of peptides with a specific PTM such as phorphorylation. (D) MRM consists of a series of short experiments in which one precursor ion and one characteristic fragment ion are selected by MS and $MS^2$, respectively. MRM is used for the detection of a specific analyte with known fragmentation properties in complex samples. (Reprinted with permission from AAAS and ref. 71.)

the chosen ion (by Q1) loses the specified neutral group input by the user. Oftentimes many possibilities exist for following a specific neutral loss because the charge of the ions dictates the mass of the neutral group; if there is question as to which charge state the ion has adopted (i.e., +1, +2, +3, +4, . . . ), then all the possibilities must be entered. For example, a phosphate group can be identified by the loss of mass 98, 49, 32.7, and 24.5 Da for charges of +1, +2, +3, and +4, respectively.

***Selected Reaction Monitoring/Multiple Reaction Monitoring*** Selected reaction monitoring (SRM), otherwise known as multiple reaction monitoring (MRM) in certain manufacturer's instruments, is as popular, if not more, than neutral loss scans because of its selectivity (precursor/fragment pair), sensitivity (lower chemical background), and quantitative capabilities. For drug discovery applications an SRM or MRM method is developed for a target compound. In proteomics this mode is often used to search for posttranslational modifications (PTMs). One caveat is that the user must predict or know beforehand the precursor and product ions. The method is optimized for a specific precursor ion (usually in positive ion mode, but can also be in negative ion mode) in Q1, and that specific ion is fragmented into smaller products inside Q2. One specific product ion of a particular *m/z* is chosen and selected inside Q3; only ions of the selected *m/z* are sent to the detector. The SRM/MRM technique can be very selective if designed to be informative as to the identity of the drug compound, and can dramatically decrease both analysis and method development time.

***Linear Ion Trap Modes*** There are numerous modes used in linear ion traps (LIT), which can be found in hybrid instruments also utilizing quadrupole analyzers, as is the case in the Q Trap. A few of the more widely used modes are discussed below.

*Enhanced MS (EMS)* This mode directs the ions from the ion source to Q3 for collection. Upon being scanned out of Q3, the ions are subsequently detected to constitute an enhanced mass spectrum.

*Enhanced Product Ion (EPI)* Precursor ions are selected in Q1 and transmitted into Q2 for CID with a reactant gas. The product ions are transmitted/collected in Q3, wherepuon they are scanned out of Q3 to constitute an enhanced product ion spectrum.

*Enhanced Resolution (ER)* Precursor ions are selected in Q1 and pass through Q2 and into Q3 without frag-

mentation. The slowest scan rate and smallest mass window are then selected to scan the precursor ions out of Q3 in order to produce a better resolved mass spectrum.

*MS/MS/MS (MS3)* After Q1 precursor ions are fragmented in Q2, the ions are transmitted and collected in Q3. Q3 ions then collide with a collision gas (such as nitrogen) and fragment, producing another generation of fragment ions, resulting in an MS/MS/MS experiment.

### 2.5 Common Mass Spectrometer Configurations

Mass spectrometry plays a vital role in numerous online, combined techniques where sample is first purified and separated on a column, with the separated components subsequently analyzed by MS. Mass spectrometers can also analyze material that has been purified offline, reducing the complexity of the mass spectrometer by removing the chromatography aspect. Both methods can be very successful, in any case, and configurations and examples are addressed below.

***Liquid Chromatography/Mass Spectrometry/Mass Spectrometry*** When a liquid chromatography system is placed inline and on the front end of a tandem mass spectrometer, the integrated technique becomes known as LC/MS/MS, one of the most widely used and most powerful MS techniques today. A SciFinder search of "LC/MS/MS and drugs" resulted in over 3600 hits in an October 2008 query. In our laboratory, we have used LC/MS/MS to identify up to 20 proteins in an equimolar protein mixture at approximately 100 fmol/protein using an Applied Biosystems 4000 Q-Trap (nanoflow) LC/MS/MS instrument [72]. LC/MS/MS is used not only in proteomics but also drug discovery [9, 10, 73, 74]. Following elution of analyte off of a column, analytes are then sprayed into the mass spectrometer and subjected to MS/MS analysis for identification.

For proteomics applications, typically the more abundant ions in each scan are subjected to MS/MS via CID (inside Q2) and transmitted into Q3; the product ions are then scanned out of Q3 into the detector. SRM or MRM experiments can be used to target specific post-translational modifications (PTMs) at specific sites of amino acids on peptides.

***Capillary Electrophoresis/Mass Spectrometry*** Although not as extensively used as LC/MS/MS, capillary electrophoresis/mass spectrometry (CE/MS) is another technique that has found a unique role in measuring chiral purity of pharmaceutical compounds. Briefly, components travel though a capillary tube containing an aqueous buffer by a DC potential imposed across the entire length of the capillary. Electrophoretic separations occur based on differences in solute mobilities. Small amounts/volumes (nanoliters) of material are typically injected into the electrically positive end of the capillary, and the charged analyte components migrate toward the negative electrode through the capillary. Typically, a UV detector is placed inline between the two electrodes near the negative electrode. The mass spectrometer is placed on the back end of the CE instrument such that analyte is eluted into the mass spectrometer.

Most studies to date make enantiomeric separation possible through the use of β-cyclodextrin or a derivatized form of β-cyclodextrin as the chiral selector.

***Gas Chromatography/Mass Spectrometry*** Gas chromatography/mass spectrometry, or GC/MS, is one of the older, simpler, and more robust MS techniques. GC/MS is widely used to analyze the molecular weight of organic and inorganic compounds that are thermally stable and volatile or can be made more volatile through reactions with the proper components. Liquid samples are injected into a heated sample port where the sample is vaporized and is carried by a gas such as helium onto the column. As the components elute from the column, the mass of the compounds is measured in the mass spectrometer. Ionization of the analyte is possible by bombarding the analyte with electrons, thereby forming ionized products that are then separated in the mass analyzer. Quantitation is also possible when using standards, where peak area varies linearly with concentration. In pharmaceutical analysis, GC/MS has been used to study dietary supplements and to quantify ephedrine alkaloids [75].

***Matrix-Assisted Laser Desorption Ionization–Time-of-Flight MS*** Matrix-assisted laser desorption ionization, better known as MALDI, is most commonly coupled to time-of-flight (TOF) analyzers. MALDI-TOF is the workhorse for most proteomic experiments in which large numbers of samples are analyzed with the intent of identifying proteins. MALDI-TOF allows users to analyze samples in a high-throughput manner, where analysis of a sample may take only a few seconds compared to an hour for a typical LC/MS run. Because only a little of the sample is consumed by this process and remains bound to the sample target plate onto which it is placed, the sample may be saved for reanalysis at a later date if needed. A plethora of studies are available in the literature regarding analysis of pharmaceutical compounds via MALDI-TOF MS. A SciFinder search for "MALDI-TOF and drugs" alone resulted in over 1400 hits in a search performed in October 2008.

***Liquid Chromatography-MALDI*** Offline coupling of liquid chromatography (LC) to MALDI-TOF is becoming increasingly popular. For example, a large protein mixture can be digested with a protease such as trypsin and then fractionated by LC, spotted at specific timed intervals on a MALDI plate, and the corresponding fractions/spots analyzed by MALDI-TOF MS/MS. As in LC/MS/MS, this fractionation process removes many competitive ionization processes among analyte ions that contributes to the preferential detection of the most abundant ions in conventional MALDI-TOF MS. LC-MALDI gives complementary data as LC/MS/MS with ESI, however, oftentimes, results in unique peptides not seen in ESI and vice versa. One advantage of LC-MALDI over LC/MS/MS with ESI is that the samples can be retained for reanalysis at a later date, whereas with conventional LC/MS/MS the sample is spent during the one-time analysis. LC-MALDI is a more recent technological advance, and a recent SciFinder search resulted in over 80 hits in an October 2008 query, much smaller compared to LC/MS/MS or MALDI of drugs.

***Surface-Enhanced Laser Desorption/Ionization–TOF MS*** Surface-enhanced laser desorption/ionization (SELDI) is a specialized form of MALDI-TOF MS in which chromatography is essentially performed on a chip (e.g., MALDI sample target plate) from which laser desorption occurs [76]. SELDI-TOF MS is primarily used as a screening tool to identify biomarkers associated with pathologies in biological samples or, in other words, used as a diagnostic tool in the early detection of diseases. In theory, each surface on the chip retains proteins according to their chemical properties. Briefly, samples originating from crude sources such as serum, plasma, urine, cell lysate, and so forth can be applied to the various surfaces and then analyzed by MALDI-TOF MS. Additionally, these types of biologically active surfaces enable molecular recognition studies such as receptor–ligand, protein–DNA, and antibody–antigen to name a few. A review article in 2003 outlined many successful studies with SELDI, some of which include SELDI as a diagnostic tool and its use in biological applications [77]. Although the technique itself has its advantages and limitations, SELDI generates patterns more so than the identification of specific proteins.

***Desorption/Ionization on Silicon Mass Spectrometry*** Desorption /Ionization on Silicon (DIOS) is a matrix-free technique where the analyte is adsorbed to a thick (micrometers), UV-absorbing porous surface on a silicon chip [78]. These surfaces can be engineered to have high UV absorptivity by using a specific etching procedure [79] and stabilizing hydrosilylation method. Some advantages of the DIOS technique include no matrix peaks in mass spectrum as with conventional MALDI, simple sample preparation, reusable sample surfaces, and low picomole detection limits [80]. Some drug analysis applications of DIOS include that of atmospheric pressure–DIOS, or AP-DIOS, and the detection of low picomole amounts of midazolam and propranolol [81] and monitoring drugs in biological fluids such as with staurosporine [82].

***Ion Mobility Spectrometry*** Ion mobility spectrometry (IMS) is a very popular technique used in national defense applications, such as in the detection of explosives and chemical agents, due to its compact size, high sensitivity, ease of use, and fast analysis speed (millisecond time scale) [83]. In pharmaceutical research, IMS is used in cleaning validation studies to confirm that a specific cleaning process has removed the active pharmaceutical drug from a specific piece of equipment.

An IMS instrument is very similar to a basic TOF design, except that drift gas is introduced in an opposite direction to that of the direction of the ion flight path. Ionization of the analyte is often initiated by a radioactive source such as $^{63}$Ni within a defined electric field and drift region. More recently, a high field asymmetric waveform ion mobility spectrometer (FAIMS) was coupled to nano-ESI for bioanalysis in drug discovery [84]. FAIMS measures differences in ion mobility at high electric fields, separating ions before introduction into the MS. This ability helps relieve the LC of needing high resolution, and in the above example LC was bypassed completely. Separation of the drug morphine from the metabolite glucuronide was accomplished prior to introduction into the MS, an important point because the metabolite can often convert back into the parent drug in the ion source of the MS [84]. Moreover, signal-to-noise (S/N) ratio saw a three-fold improvement.

***Accelerator MS*** Accelerator MS, or AMS, is best known for its use in $^{14}$C dating in archeology, for example. AMS uses very small sample amounts (sub-milligram), concentrations between $10^{-12}$ and $10^{-16}$, and analysis time of less than 1 h. Samples with ages of tens of thousand of years can be determined within these paramaters above. Other areas of importance utilizing AMS include atmospheric processes, ocean circulation, and even biomedical studies. Isotopes such as $^{10}$Be, $^{36}$Cl, $^{26}$Al, $^{41}$Ca, and $^{129}$I have also been used in dating rock (for Be, Cl, and Al), studying metabolic processes in living systems (Al), and tracing nuclear waste migration from nuclear storage and reprocessing plants as mentioned in recent review articles [85, 86]. In short, AMS most often uses an electrostatic tandem accelerator to count indi-

vidual atoms from rare isotopes from a sample following acceleration energies in the range of 0.2–40 MeV. The technical aspects and common applications of AMS have been published previously [87]. Sensitivity is dramatically increased due to improvement in S/N by decreasing the background levels substantially.

With regard to the current relevant application of biomedicine, isotopes such as $^{3}H$ and $^{14}C$ are common. The use of AMS is limited in this field, however, due to the cost and size of the instrumentation. There is a current push to reduce the size and complexity of AMS instrumentation, thereby making this technique more applicable to biomedical studies. One study showed that AMS provides a factor of $10^3$ improvement in sensitivity with milligram-sized $^{3}H$ samples compared to conventional decay counting [88]. Another study used $^{26}Al$ as an AMS isotope to study the metabolism of aluminum under physiological conditions [89]. Moreover, $^{41}Ca$ has been used as an isotope to study calcium metabolism in the skeleton [90].

## 3 SAMPLE PREPARATION

A plethora of preparation methodologies exist for treatment of pharmaceutical specimens prior to analysis in a mass spectrometer, depending on the sample complexity. The importance of sample preparation cannot be overemphasized because the cost and quality of the data are in fact dependent on the state of the sample prior to analysis. Discussed below are several preparations commonly used in chromatographic analysis and drug development [91]. However, the list is not intended to be an all-inclusive one containing every preparation in the literature. The techniques listed below are extraction processes. Preextraction and postextraction methods are not addressed in this section, however, they are equally important. Preextraction steps primarily deal with the addition of internal standards and sampling, and postextraction steps include sample treatment such as concentration, pH, and solubility.

### 3.1 Protein Precipitation

Protein precipitation (PPT) is a very established technique used, in many cases, to remove proteins from samples containing small molecules in preparation for analysis. PPT often uses organic solvents, heat, salt, or acid to reduce the protein concentration. A mixture of organic solvent(s) and treatment agent(s) is agitated to catalyze protein aggregation. The analyte (e.g., small molecule) remains immersed in the supernatant and can be separated from the mixture via filtration or centrifugation.

### 3.2 Solid-Phase Extraction

Solid-phase extraction (SPE) operates under the same principle as separation by chromatrography. As in chromatrography, the most common mode of SPE is reverse phase. The goal of SPE is the separation of analyte from biological matrix via retention and subsequent elution. In reverse-phase SPE, organic molecules bind to a solid support as an aqueous phase containing the organic molecules passes by. The most retentive molecules bind to the column, whereas the least retentive molecules are in higher abundance in the flowing mobile aqueous phase. Many reviews have been written detailing applications of SPE [92].

### 3.3 Liquid–Liquid Extraction

Liquid–liquid extraction (LLE) is applied to small-molecule recovery and identification. Efficient analyte extraction is obtained when a targeted small molecule diffuses between two immiscible organic layers upon mixing. Choice of organic solvents/additives, boiling points, containers, and automation are all important factors that should be carefully weighed before a final decision.

### 3.4 Other Sample Preparations

Turbulent-flow liquid chromatography (TF-LC) is a form of online chromatography that offers higher flow separations because it is not limited by diffusion as in traditional chromatography separations. The time scale of the experiment can be much faster, higher resolved peaks obtained, and less ionization suppression [93]. TF-LC often allows for little or no prior sample preparation methodologies other than filtration or centrifugation because complex samples can be injected onto the column. Other high-throughput, online sample cleanup strategies for metabolites include microdialysis [94] and liquid-phase membrane extraction [95].

## 4 ROLE OF PROTEOMICS IN PHARMACEUTICAL ANALYSIS

Pharmaceutical analysis encompasses a wide variety of targeted molecules and subsequent applications. One class of compounds is proteins. Mass spectrometry (e.g., MALDI and ESI) has revolutionized the study of proteins as seen by the shear number of articles in the literature in the past 15 years. Many review articles have been written in regard to numerous proteomes and biomarker discovery [96–98], drug discovery [99], PTMs [100], and quantitation [101, 102]. Approaches involving

both gel electrophoresis and gel-free techniques can be readily found in the literature [103, 104]. After a protein is identified, questions then arise as to relative abundance in control/diseased samples, PTMs at specific amino acids, and more generally how to process the amount of data that can be generated in a typical MS experiment. These are all important issues in pharmaceutical proteomic analysis.

### 4.1 Protein Identification

Protein identification is one of the first and most often requested items by researchers to personnel in our MS proteomics facility (and in most proteomics facilities), whether the sample is in the form of a stained gel band or in solution. Although gel electrophoresis of proteins gives information such as molecular weight range of the proteins and differentiates the presence of proteins between samples (e.g., diseased versus control), they do not offer the ability to identify each protein; techniques such as Edman sequencing and MS are required to either identify by protein sequence or with Web databases, respectively. N-terminal Edman sequencing can be very expensive, ranging in price from a few dollars to greater than $20.00 per amino acid for any given peptide or protein. MS is routinely used for protein identification, due to the low cost per sample (not per amino acid) and rapid turnaround time.

Bottom-up and top-down approaches (identification based on peptides or proteins, respectively) dominate proteomic research using MS, with more top-down approaches being introduced each year with improving commercial instrumentation [105, 106]. Identification by MS through bottom-up proteomics relies on the formation of peptides from enzymatic cleavage and their corresponding ion fragmentation patterns for amino acid sequence (MS/MS). The cost of identifying a protein by MS as opposed to Edman sequencing can be substantial. For example, a 50-amino-acid protein might cost up to $1000 for complete sequence information using Edman sequencing techniques, whereas it might cost only $50 for identification by MS. The assumption for MS analysis is made that the protein has previously been sequenced, or "known," and is found in a published protein database such as the National Center for Biotechnology Information (NCBI). Much more additional work would be required to positively identify an unknown protein by MS, whereas N-terminal protein sequencing is not dependent on databases and can positively identify protein sequence.

When surveying a large number of samples and wanting to quickly identify proteins in a cost-effective manner, MS (most often MALDI-TOF) is the preferred technique. More information is provided in Section 4.4 in regard to the various methods employed in MS protein identification via software and database matching.

In most cases, only after protein identification does PTM identification play a key role. In the section below, case studies are described that detail the identification of several common types of PTMs in identified proteins.

### 4.2 Posttranslational Modifications

The identification of posttranslational modifications (PTMs) is one of the more recent and biologically important advances in proteomics and mass spectrometry. No longer does an experiment have to conclude at the identification of a protein but rather can continue to the investigation of site-specific PTMs and, to some extent, the relative quantitation of these modifications. It is well known that PTMs play a vital role in protein recognition studies. One of the challenges is identifying PTMs in vivo when a heterogeneous mixture may be present and/or the PTM form is in low abundance relative to the unmodified form. Moreover, a protein may only have certain PTMs when it is in a certain biological or stressed state. Proteomics encompasses PTMs for many reasons, one being that PTMs can act as molecular switches to modify protein biological activity. The end result is that PTMs can be very difficult to identify and are dependent on the state of the protein or sample prior to extraction, isolation, and/or purification.

There are close to 200 mammamlian PTMs studied in the literature, however, we are focusing on 3 of the more popular ones, that is, phosphorylation, glycosylation, and nitration. Any PTM adds a mass shift, either positive or negative, to an amino acid. Mass accuracy is higher in the lower mass region of a mass spectrometer for peptides as opposed to whole proteins, thereby making the bottom-up proteomics approach the more common platform for protein and PTM identification.

***Phosphorylation*** Protein phosphorylation is one of the most abundant and most studied PTMs known in mammalian cells, as evident in a recent review article [107]. Phosphorylation occurs principally on serine, threonine, and tyrosine residues [108]. Routine identification of phosphorylation sites is usually accomplished via MS/MS, which is capable of identifying the amino acid modification site within a peptide or protein, as opposed to MS, which only gives the molecular weight. In the case of phosphorylation, the addition of a phosphate group results in a molecular weight increase of 80 Da ($HPO_3$). MS is useful in this case for identifying the mass shift, although MS/MS is useful in giving pseu-

**Figure 2.** Predominant loss of phosphoric acid (98 Da) at *m/z* 1964.1 originates from a phosphorylated peptide at *m/z* 2062 under postsource decay (PSD) conditions in a MALDI-TOF/TOF mass spectrometer. Peptide sequence can be deduced from the fragment ions at multiple masses observed lower in the mass region.

dosequence information via fragment ions that ideally show the loss of the phosphate group from a specific amino acid site. Figure 2 demonstrates the typical predominant loss of phosphoric acid ($H_3PO_4$) (98 Da due to additional water loss of 18 Da) at *m/z* 1964.1 from the phosphorylated peptide at *m/z* 2062 during postsource decay (PSD) or collision-induced dissociation (CID) in a MALDI-TOF/TOF mass spectrometer. Peptide sequence can be deduced from the fragment ions observed at multiple masses lower in the mass region. Because of the likelihood of false positive using automated software programs to identify the phosphate group in an MS spectrum, it is still the norm to manually interpret the MS/MS spectrum for the loss of phosphoric acid as well as additional novel fragment ions such as phosphotyrosine at *m/z* 216.

A typical MS phosphoprotein standard is α/β-casein, which has several phosphorylation sites. In order to reduce complexity, it is very common to isolate/purify a phosphopeptide or phosphoprotein before MS analysis, and one method includes the use of immobilized metal affinity chromatography (IMAC) [109]. IMAC columns are the most common method of phosphopeptide enrichment to date and are incredibly simple to use. Selectivity of IMAC toward phosphate groups is governed by electrostatic interactions between the positively charged metal ions and the negatively charge phosphate groups. Most manufacturer protocols state that the entire process for phosphopeptide sample loading, binding, and eluting is on the order of approximately 10 min. Improvements to both offline and online IMAC methods have gradually been made over the years, ranging from choice of column material to choice of metal ion. The resultant phosphopeptide-enriched sample can then be analyzed by MALDI or ESI.

One alternative to IMAC is metal oxide affinity chromatography (MOAC) mircotips, which use support materials such as titanium dioxide [110] or zirconium dioxide [111] in combination with mass spectrometric analysis of the phosphopeptides. Another option for phosphopeptide enrichment is the use of strong cation exchange chromatography (SCX) [112].

Many other articles have been written detailing methods for identifying phosphorylated peptides through both unique sample preparation and MALDI-TOF or LC/MS analysis. Li and co-workers have investigated different ionic-liquid matrices for improved phospholipid analysis, where the extent of prompt fragmentation is decreased and alkali–metal–ion adducts are increased [113]. Asara and co-workers used ammonium salts to enhance the detection of phosphopeptides in MALDI MS [114]. Yang and co-workers have combined an alternative matrix, 2′, 4′, 6′-trihydroxyacetophenone (THAP) with diammonium citrate to aid in the detection of phosphopeptides generated from proteolytic digestion by MALDI MS [115]. The use of negative ion mode in MALDI, which detects negatively charged ions, has also been exploited to enhance detection of phosphopeptides [116]. Moyer and co-workers have investigated the fragmentation of phosphopeptides by atmospheric pressure MALDI and ESI/ion trap mass spectrometry and have proposed possible gas-phase mechanisms of dephosphorylation of phosphotryrosine [117]. A popular loss of 98 Da was observed

from phosphotyrosine, phosphoserine, and phosphothreonine. DeGnore investigated the fragmentation of phosphopeptides in an ion trap mass spectrometer as well, as seen in Figure 3, noting that the loss of phosphoric acid ($H_3PO_4$) from phosphoserine does not depend on the charge state [118].

***Glycosylation*** Another abundant PTM of proteins is that of glycosylation. Glycosylation is the process by which a glycan is covalently bound to a protein. According to Apweiler et al. [119], as many as 50% of all proteins are glycosylated. Fortunately, protein glycosylation occurs at specific and predictable amino acids. N-linked glycosylation occurs when a glycan is bound to the side chain of asparagines. However, this only occurs when the asparagine is of the consensus sequence Asn-X-Y where X is any amino acid except proline and Y is serine, threonine, or cysteine. O-linked glycosylation occurs when a glycan is covalently bound to serine or threonine. This can occur regardless of the amino acid sequence of the protein.

Unfortunately, the analysis of glycoproteins, particularly intact, is difficult due to the heterogeneity of the glycan moieties. Often there is no one individual method for performing mass analysis on glycoproteins, but rather a variety of different methods may be employed by the investigator. Both MALDI-TOF MS and ESI MS have been routinely used for analysis. ESI MS has the advantage in that it can be coupled to LC or CE.

Because glycopeptides often have lower ionization efficiency than their nonglycosylated counterpart, enrichment is often a requirement prior to analysis. Glycopeptides can be isolated with the use of lectin affinity methods [120]. LC columns can be fabricated in which the stationary phase contains a variety of lectins that allows not only for the capture of glycopeptides a nd glycoproteins but also allows for the separation of the heterogeneous glycopeptide/glycoprotein mixture [121, 122].

Due to the chemical complexity of glycans, higher order MS scans must often be performed in order to elucidate their chemical structure. MALDI-TOF/TOF and triple-quadrupole ESI mass spectrometers only allow for MS/MS analysis. Ion traps, however, allow for higher order MS analysis such as $MS^3$. Recently, hybrid mass spectrometers, such as the combination of triple-quad and linear ion traps, have become popular and allow for $MS^3$ analysis. This is especially popular in elucidating the structures of branched glycans [123].

***Nitration*** Lately there has been an interest in the biological role of tyrosine nitration to 3-nitrotyrosine. The nitro group on tyrosine is a PTM, which is the result of oxidative stress and therefore has the potential as a biomarker for oxidative stress of proteins [124]. 3-Nitrotyrosine has been associated with many human diseases including Alzheimer's disease [125], atherosclerosis [126], inflammatory diseases [127], and stroke [128]. Although there is still some debate as to the mechanisms by which nitrotyrosine is formed in vivo, it is believed to result from the presence of peroxidases in the presence of hydrogen peroxide and nitrite [129].

3-Nitrotyrosine-containing proteins that have been separated via two-dimensional gel electrophoresis can be visualized by performing a Western blot using commercially available 3-nitrotyrosine antibodies [130]. However, positive identification of 3-nitrotyrosine-containing proteins can only be confirmed by MS/MS analysis, which also allows for locating the specific tyrosine within a protein that has been nitrated.

Both ESI and MALDI-TOF MS have been used for the direct analysis of 3-nitrotyrosine-containing proteins [131]. Often 3-nitrotyrosine-containing proteins are first enriched in order to reduce the complexity of the sample and thereby improving the quality of the MS data. Enrichment may be performed using immunoaffinity methods. Typically proteins of interest are first digested with a protease and then the resulting 3-nitrotyrosine peptides are captured through the use of immunoaffinity beads [132]. 3-Nitrotyrosine peptides may also be selected for by first reducing 3-nitrotyrosine to 3-aminotyrosine, which is then coupled to a cleavable biotin affinity tag [133].

Nitration of tyrosine results in a molecular weight increase of 45 Da. The resulting molecular weight for 3-nitrotyrosine is not isobaric with any other amino acid and therefore allows one to easily identify and locate 3-nitrotyrosine within a peptide sequence via MS/MS. However, the choice of ionization will have a major effect on the mass spectral results. Analysis of 3-nitrotyrosine-containing peptides by LC/MS/MS, which incorporates the use of ESI, typically results in the nitro group on tyrosine remaining intact during ionization and CID [134]. The MS/MS of a 3-nitrotyrosine-containing peptide by ESI is illustrated in Figure 4. A mass difference of 208 Da is observed between fragment ions $y_9$ and $y_{10}$, which corresponds to 3-nitrotyrosine. Most protein database search software such as MASCOT and SEQUEST allow for the addition of modified amino acids.

Unlike ESI, MALDI ionization of 3-nitrotyrosine yields a variety of photodissociated products. This unique characteristic of 3-nitrotyrosine is believed to be the result of photodissociation caused by the wavelength of the laser light being very close to that of the absorption maximum wavelength for 3-nitrotyrosine as reported by Petersson [135]. MALDI MS typically yields ions of the type $[M+H]^+$ along with the photodis-

**Figure 3.** Loss of $H_3PO_4$ (98 Da) is not charge state dependent for phosphoserine-containing peptides. (A) $MS^2$ spectrum of the singly charged ion at *m/z* 1115.5. (B) $MS^2$ spectrum of the doubly charged ion at *m/z* 558.3. (C) $MS^2$ spectrum of the triply charged ion at *m/z* 372.5. Fragmentation of all charge states exhibits a loss of $H_3PO_4$. Fragments with an asterisk indicate loss of 17 Da (likely $NH_3$) from corresponding *b* or *y* fragment. (Reprinted with permission from Elsevier and ref. 118.)

**Figure 4.** MS/MS of a 3-nitrotyrosine-containing peptide under ESI conditions. A mass difference of 208 Da is observed between fragment ions $y_9$ and $y_{10}$, which corresponds to 3-nitrotyrosine. (Reprinted with permission from John Wiley & Sons and ref. 135.)

sociated products $[M+H-16]^+$, $[M+H-30]^+$, and $[M+H-32]^+$, which corresponds to $NO_2 \rightarrow NO$, $NO_2 \rightarrow N$, and $NO_2 \rightarrow NH_2$ by the loss of oxygen as reported by Sarver [136]. This is illustrated in Figure 5, a MALDI-TOF mass spectrum of angiotensin II in which the tyrosine has been nitrated to 3-nitrotyrosine. The peak at *m/z* 1341.7 is that of the nitrated angiotensin and those at *m/z* 1309.8, 1311.8, and 1325.8 are those of the photodegraded products formed during the ionization process.

### 4.3 Quantitation

Mass spectrometry is not well known for supplying quantitation data because it most often depends on the ionization potential of compounds that can dramatically vary, regardless of the amount of each analyte in a mixture. Progress is being made, however, and the most common techniques utilizing mass spectrometry use isotope chemistry.

***Isotope-Coded Affinity Tags/Isobaric Tags for Relative and Absolute Quantitation*** Rapid identification of proteins has been one of the most important attributes of mass spectrometry for the advancement of proteomics and biological systems. However, in order to completely understand the functions of identified proteins in a system, it is also important to understand the expression of these proteins. Isotopic labeling of peptides and proteins followed by mass spectral analysis has become the most common method for quantifying peptides and proteins by mass spectrometry. Several methods such as isotope-coded affinity tags (ICAT) and isobaric tag for relative and absolute quantitation (iTRAQ) have been commercialized and are readily available as kits for the quantification of peptides and proteins. Recently, these methods have been adapted for the quantification of amino acids, thereby allowing one to perform amino acid analysis by mass spectrometry.

The use of ICAT reagents was first reported by Aebersold [137] in 2001. ICAT reagents are comprised of three parts: an iodoacetamide group for covalently binding the reagent to the thiol group of cysteine residues, an isotopically labeled linker for MS quantification, and a biotin tag to isolate the ICAT-reacted peptides. The linker of the ICAT reagents incorporates either hydrogen or deuterium as the stable isotope. Recently, ICAT has been reformulated such that nine carbons are exchanged in order to obtain a molecular weight difference of nine mass units. Figure 6 illustrates the chemical structure of this ICAT reagent. Peptides and proteins can be differentially labeled by labeling one set of proteins with the carbon-12 linker and another protein set with the carbon-13 linker. The relative ratios

**Figure 5.** Nitrated angiotensin is observed at *m/z* 1341.7, and peaks at *m/z* 1309.8, 1311.8, and 1325.8 are those of the photodegraded products formed during the ionization process in a MALDI-TOF/TOF mass spectrometer in our MS laboratory at University of Texas Medical Branch.

**Figure 6.** Chemical structure of an ICAT molecule.

of the $^{12}$C- to $^{13}$C-labeled peptides thereby correspond to the ratios of the peptides in the two different sets.

Recently, iTRAQ reagents have been replacing ICAT as the method of quantification [138, 139]. Unlike ICAT, which allows for only two sets of proteins to be differentially labeled, iTRAQ allows up to eight different sets of peptides or proteins to be labeled. This is accomplished by covalently attaching an isobaric tag to an amine reactive group of a peptide. The isobaric tag consists of a reporter group and a balance group. The reporter group ranges in mass from 113 to 121 mass units and the balance mass ranges from 192 to 184 mass units, thus giving a total mass of 305 mass units for each reagent. Because the total mass of the tag is identical for each reagent, identical peptides in two different sets that are differentially labeled will also have equal masses. However, during MS/MS fragmentation, quantification is measured by the difference in ion abundance of the reporter groups.

***Stable Isotope Labeling Amino Acids in Cell Culture*** Other methods for incorporating stable isotopes have been reported. Stable isotope labeling amino acids in cell culture (SILAC) allows for the incorporation of isotopically labeled amino acids into cell cultures [140, 141]. The growth media of one cell culture will contain normal amino acids while the growth media of another cell culture will contain an isotopically modified amino acid. Chemically identical peptides can be differentiated by the mass spectrometer because of their amino acid mass differences and therefore observed as peptide pairs. The ratio of peak intensities for the peptide pairs corresponds to the ratio of their protein abundance.

### 4.4 Bioinformatics

Bioinformatics is a very broad subject, therefore, we will briefly focus only on its application to MS data in the biopharmaceutical proteomics arena and, more specifically, in those topics that are more practical to the actual "users" of MS instrumentation.

Generally speaking, bioinformatics has progressed proteomics to the field it is today, that is, one that includes a large amount of data analysis, handling, interpretation, and storage. Advancements in the computer industry are largely responsible for the advent of bioinformatics in many areas of science. In the 1970s, the use

of mass spectrometers on a larger level was beginning to emerge. However, computers and user interfaces did not exist in the form we know and use today. Consequently, in the last 25 years mass spectrometry has grown not only as a result of MS instrumentation advancements but also as a result of computer hardware and software innovations.

***Database Platforms*** There are many options in the choice of database platform for protein identification, and many are dependent on mass spectrometer manufacturer. Some of these software packages include Mascot [142], PepProbe [143], OMSSA [144], RMET-Luck [145], SEQUEST [146], and Tandem [147]. Each platform usually requires various parameters to be completed by the user. Some parameters are dependent (e.g., mass tolerances) and others are independent (e.g., database choice such as NCBI, SwissProtein, MSDB; enzyme; variable/fixed modifications) on the instrumental conditions. Many novel platforms (i.e., algorithms) have been written for spectral peak analysis and for matching experimental data to theoretical data, and a more detailed description of the latest techniques can be found elsewhere [103].

***Standards and Data Management*** Because of the enormous amount of data generated by MS proteomic experiments, one typically only views a list of identified proteins and sometimes identified peptides in published research articles. The raw data is often omitted, and other critical data sets either buried in the supplemental data section online or also omitted from the print publication. The Association of Biomolecular Resource Facility (ABRF) (http://abrf.org) recently published guidelines it would prefer to see implemented in scientific journals, but each journal has its own set of guidelines for submission of publications. Moreover, from the standpoint of commercial MS instrumentation and software packages, many are unique in the data file extensions used, making it sometimes difficult to disseminate data in a universal fashion.

There has been an ongoing initiative throughout the last few years to improve the standardization of data distribution, which would simplify data sharing, an especially important factor in cases where large proteomic studies are being conducted by multiple institutions and where data is submitted and combined in online databases from various researchers with MS instrumentation from different manufacturers. The Proteomics Standards Initiative (PSI) (http://psidev.sf.net/), an extension of the Human Proteome Organization (HUPO), already has defined the use of software language, XML, as a standard for MS data [148]. XML offers the primary advantage of being shared across multiple software platforms. Other common formats include FASTA, mzXML, and pepXML. BioPAX (http://biopax.org) is an alternative to the PSI standard and is defined in both metabolic network and molecular interaction levels [97].

Other techniques have been introduced to reduce the amount of data gathered in a typical MS experiment in proteomic applications, and many of them involve improvements made to the very popular SEQUEST search engine. Beer introduced Pep-Miner for clustering MS/MS data in order to increase peptide identification with higher confidence [149]. There are a number of other statistical approaches also made to benefit SEQUEST for improving peptide/protein identification confidence while reducing false-positive rates [150, 151].

## 5 DRUG METABOLITES

Metabolite is a term applied to a compound that is typically pharmacologically less active than its parent compound, although this is not always the case. Over the years, mass spectrometry has grown tremendously in this field alone by allowing the analysis of trace amounts of compounds, such as metabolites, in complex mixtures. One of the earliest MS techniques of choice was GC/MS because of the MS requirement for molecules to be in the gas phase. As ionization techniques for MS evolved, however, the coupling of LC to MS has become the dominant analytical instrument for the study of pharmaceutical compounds such as metabolites in biological matrices. A recent review article details several LC/MS/MS applications for metabolite structural information such as ziprasidone for the treatment of schizophrenia and voriconazole as an antifungal agent to treat multiple pathogens [152].

Drug degradation products in pharmaceutical formulations are also widely studied by LC/MS, and numerous examples can be found in review articles [153]. Common degradation products originate from processes such as oxidation, rearrangement, hydrolysis, dehydration, and adduct formation, to name but a few, and are commonly analyzed in media such as human plasma. Oftentimes products can be formed that are combinations of the above-mentioned processes, further complicating analysis by MS. These cases then rely heavily on tandem MS ($MS^n$) techniques to elucidate structure. It is becoming more common to develop a single MS platform that simultaneously analyzes for more than one parent drug compound or its associated metabolites. Many case studies have been compiled in a recent review article [74].

Another review article was written on systematic LC/MS metabolite identification in the drug discovery

industry, focusing on tandem MS methods for the identification of compounds [154]. Many aspects are addressed, such as targeted product ion analysis, determination of modification sites, and identification of dosed compounds, with an emphasis on specific MS modes such as collecting precursor ion scan and neutral-loss data, product ion analysis of potential metabolites, structural determination by $MS^n$, and accurate mass measurement.

More recently an article was published detailing the use of the LTQ/Orbitrap, at a resolving power of 60,000 and high mass accuracy less than 2 ppm, for human liver microsomal metabolites of carvedilol [155]. Also, rat tissue sections from liver, spleen, and muscle were analyzed for erlotibiv and its metabolites with a MALDI quadrupole TOF mass spectrometer [156]. In addition, this study examined the feasibility of obtaining quantitative data from tissue sections analyzed by MALDI MS/MS.

More novel MS techniques have recently been applied to metabolite identification. Desorption electrospray ionization (DESI), a newer atmospheric pressure ionization technique introduced by Cooks and coworkers, can be used to quickly ascertain the molecular weight of metabolites from complex biological matrices such as urine [157]. Also, electrospray photoionization (ESPI) LC/MS was used for analyzing cyclodextrin and pharmaceuticals and their binding interactions [158]. All components of a mixed-polarity liquid sample were measured using this new ionization technique. Binding constants were also determined for cyclodextrin to various compounds.

## 6 EMERGING FIELDS FOR DRUG ANALYSIS BY MS

As is the case in all areas of science, there are specialty areas within fields that drive technology and engineering further into the future—the incorporation of mass spectrometry into biopharmaceutical science is no different. The advent of MS and its vital role in drug discovery is so common now that other applications are available for pharmaceutical compounds. Several budding biopharmaceutical fields utilizing mass spectrometry are discussed below, with the caveat that this section only serves as a brief introduction using several examples from the literature.

### 6.1 Environmental MS

Environmental MS often refers to the field of contaminants, whether they are present in soil, sludge, water, or atmosphere. Many reviews have been written on pharmaceuticals and the environment and several examples will be highlighted in this section [159, 160].

One field that garners a lot of public attention is the amount of antibiotics in wastewater; many cases have been studied where wastewater treatment did not completely remove antibiotics such as erythromycin, roxithromycin, to name but a few compounds. The technique of choice is often SPE-LC/MSMS, that is, solid-phase extraction (SPE) combined with LC/MS/MS. A mixture of antibiotics was analyzed in two studies that found concentrations in the low microgram/liter range in wastewater [161] and in the microgram/kilogram range in sewage sludge [162]. Another study found several antibiotics such as four macrolide antibiotics and six sulfonamides in the low nanogram/liter range [163]. LC/MS/MS has also been used to identify pharmaceuticals such as erythromycin, carbamazepine, fluoxetine, and diphenhydramine in reclaimed water used for irrigation [164]. Although there are a plethora of methods utilizing LC/MS/MS for pharamaceuticals, there are fewer using GC/MS and CE/MS; most GC/MS methods in the literature have comparable sensitivity limits to LC/MS/MS, however, CE/MS sensitivity is generally 1 to 2 orders of magnitude lower than most LC/MS/MS methods.

Other contaminants gaining notoriety in environmental MS analysis and discussed in detail elsewhere include sunscreens/organic UV filters, drinking water disinfection by-products, old and new flame retardants, benzotriazoles, naphthenic acids, pesticides, perchlorate, and last but not least, microorganisms [160]. Microorganisms have gained particular importance since the threat of bioterrorism became more widespread, and Fenselau has pioneered much of the MS-based identification of different organisms using both ESI and MALDI ionization techniques [165–167].

### 6.2 Forensic MS

A SciFinder search in July 2011 resulted in over 3600 hits when using the terms "MS," "forensics," and "drugs." Forensic analysis is a very broad field encompassing DNA analysis, trace evidence, and drugs [168]. Many reviews have covered these topics. The scope of this section, however, is to introduce some choice examples of drugs or pharmaceutical compounds relevant in forensic MS analysis. It is important to keep in mind that with most of these drug analyses in forensic MS, the medium in which the drugs are present can be very complex and may require one or more sample preparation strategies to extract and identify the compounds in the matrix (e.g., body fluids).

Forensic science has long used GC/MS for the analysis of volatile compounds, and even nonvolatile

compounds that are made more volatile through the use of chemical derivatization. The identification of ethanol in biological fluids such as blood is very common in postmortem procedures. The identification of narcotics such as morphine, heroin, cocaine, methadone, and their associated metabolites have been found in urine, blood, saliva, and even hair using LC/MS/MS techniques such as SIM/MRM in combination with sample preparation strategies such SPE and, more recently, solid-phase microextraction (SPME). Recently, anabolic steroids and their associated metabolites have been detected and quantitated in hair by GC/MS/MS [169].

### 6.3 Miniaturization

Miniaturization can increase throughput and drive down costs in many service facilities, however, the cost for developing miniature technologies can be high. The need to miniaturization mass spectrometer platforms is driven in many cases by the aspect of field portability. Miniature and field-portable MS instruments can be very useful in both military and civilian settings, either in a battlefield environment or in a hospital room. In the first case, chemical weapons testing can be done with miniature ion trap mass spectrometers made popular by Cooks at Purdue University who wrote a review article describing the various miniature MS analyzers available [170]. In the second case, Cotter and co-workers at Johns Hopkins University School of Medicine are designing miniature instruments that could be used either in a hospital room setting to detect potentially known biomarkers for disease [171] or in a mobile laboratory to identify bacterial organisms such as *Bacillus* spores [167] , or even for Mars surface analysis [172]. In all cases the application drives the need for miniaturization of existing technologies.

In the case of biopharmaceutical analysis, miniaturization many times takes the form of sample preparation methods that can increase throughput at lower costs per sample in a more timely fashion. This part can be extremely valuable in the case where drug candidates or potential biomarkers are being screened. Some key players in many miniature sample preparation platforms include microfluidics as well as chromatography. Other advances in MS instrumentation can also benefit pharmaceutical science by improving the mass accuracy, which can reduce false-positive rates for small-molecule and drug identification.

The most common form of miniaturization used across research laboratories is the use of 96-well sample plates fitted for automated microliter or even nanoliter volume extraction, increasing throughput while reducing cost. For example, less solvent waste is generated in this format, which will reduce laboratory waste disposal expenses. These well-plates can then be transferred, either directly or indirectly, into LC/MS or MALDI-TOF mass spectrometers for rapid analysis.

The advent of analyzing smaller amounts of material has also directly affected LC/MS instrument manufacturing, that is, in the form of nanospray ESI tips and nanoflow LC pumps (e.g., nano-LC/MS/MS). Identification can be made on an assortment of compounds through the injection of only a few microliters onto a capillary HPLC column, with solvent flow in the nanoliter/minute regime. The analysis of very small volumes of material is very convenient in cases where the user is searching for PTMs and may have to run several MS experiments to confirm the presence of a modified amino acid on a peptide, for example. Having enough sample for multiple runs also allows for experimental precision to be calculated, and the sample can be saved for analysis at a later time.

## 7 CONCLUSIONS AND FUTURE OUTLOOK

Mass spectrometry has experienced tremendous growth throughout numerous scientific disciplines in the last few decades. In the early days of MS, instruments were so large that they occupied entire rooms. Nowadays, there are many options in regard to the type and size of available instruments depending on the application. Advancements in MS technology have pushed the field into applied biological sciences and pharmaceutical research in such a way that was barely imaginable many years ago. Moreover, MS instrumentation is at the point where almost any researcher can quickly learn how to use a mass spectrometer because the software is so user friendly and the hardware is well engineered, much different than when MS instrumentation was primarily used by only experts in the field in the 1950s to early 1970s. The advent of MALDI and ESI ionization techniques, as well as TOF, quadrupole, and ion trap analyzers, have totally transfigured MS with the detection of higher mass molecules, which pushed fields such as proteomics to far horizons. In biopharmaceutical research, low concentrations of analytes can now be detected in very complex mixtures and environments. Clearly, the field of mass spectrometry will continue to play a starring role in this area as well as many other scientific disciplines in the foreseeable future.

# MOLECULAR SCREENING FOR THERAPEUTIC AGENTS

R. Damoiseaux
*Molecular Screening Shared Resource, California NanoSystems Institute, University of California, Los Angeles, California*

## 1 INTRODUCTION

### 1.1 Historical Overview

Sequencing of the human genome in 2001 provided a conceptual infrastructure for understanding the cellular processes fundamental to life and health [1]. Following the advances in decoding the human genome at the sequence level, deciphering the function of individual proteins encoded by the genome and elucidating their respective biochemical pathways is now well on its way. As a result, cellular processes and their involvement in disease and discovery of therapeutic compounds for the various disease indications are becoming better understood. Consequently, the postgenomic era filled the drug target pipeline of the pharmaceutical industry with an unprecedented number of targets [2, 3].

In the pregenomic era, screening for therapeutic compounds of up to 10,000 compounds per diem was the scientific standard for drug discovery until the 1980s and 1990s. As more and more drug targets became available, drug discovery companies began pushing for more intelligent, productive, high-precision discovery [4]. A solution to these needs was molecular screening, the combination of molecular biology and drug screening. By means of molecular biology, it became possible to engineer assay systems that mimic a disease system and subject it to screening for therapeutic compounds [5].

Molecular screening soon became automated and enabled the use of very complex assay systems without the personnel burden normally associated with screening for bioactive compounds. [6, 7] In addition to saving labor, automation offered other compelling advantages. Experiments could be reproduced perfectly and performed on a much larger, more expansive scale. It became feasible to transfer experiments from low- to high-throughput platforms for screening of large compound sets and then transfer the experiments back again for hit validation and characterization purposes.

At the beginning of the transition to automation, most of the assays were biochemical. These assays were typically performed on single isolated proteins. Rapidly, the technology expanded to accommodate assay systems based on cells. Now, even whole organism platforms [8] are a promising new possibility, and current automation platforms are capable of handling complicated experimental protocols, opening the door to the use of molecular screening in general basic research.

These research applications of screening include functional genomics screens using small interfering ribonucleic acid (siRNAs) [9], short hairpin RNA (shRNAs) [10], and overexpression libraries [11], just to name a few. This chapter gives an introduction to the general concepts of molecular screening as they relate to discovery of therapeutic agents and highlight some research applications of molecular screening. It will give a general introduction to the concepts of molecular screening, provide an overview of the general work flow, outline different screening approaches, give an overview of the assay development and validation process, and discuss the basic readouts for assays. Then we will have a close look at compound libraries that can be

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

paired with the assays during screening. We will have a look at the results, how to explore the properties of the resulting hits and how to deal with false positives. Later on, target discovery will be examined, in particular of using small molecules and siRNAs, shRNAs, and complementary deoxyribonucleic acid (cDNAs), which rely on similar concepts and could be said to use molecular screening for research purposes. Last, but not least, we shall have a look at how the data acquired during screening can be stored, managed and combined, and mined for maximal efficiency.

### 1.2 Screening for New Chemical Entities (NCEs)

The main objective of screening for NCEs is to identify a therapeutic compound out of a collection of compounds by acquiring high-quality data of therapeutic biological relevance—in the shortest period of time and for the least amount of money possible.

The general historic work flow is to select a therapeutic protein target (not pathway or phenotype), then design an assay around it, execute the screen, validate the hits, and develop lead compounds. This work flow is often abandoned as a result of the completion of the genome project. We have more potential targets than ever available, targets where purified protein might not be available (as is the case with many membrane proteins) or all scenarios where players of the pathway are not known. Consequently, it is unavoidable to augment the arsenal of assays with, for example, pathway-specific screening strategies based on cell-based assays. The development away from the biochemical assays toward more inclusive, cell-based platforms culminated in the emergence of black-box approaches, which rely on, for example, a phenotype observed in cells or even whole organisms as readout. With the increasing complexity of the assay system, it has become equally more difficult to elucidate the mode of action or the target of a hit compound. However, not only is the screening for compounds now automated but also the target discovery, which makes these approaches more attractive than at the beginnings of molecular screening.

### 1.3 Screening as a Research Tool

Screening has made its evolution from a very specialized tool in the drug discovery of the pharmaceutical industry into a research tool that is now found not only in industry but as well at some universities [12]. This transformation has changed molecular screening on the scientific as well as the practical level.

On the scientific level of this evolution, the advent of siRNA, shRNA, and other techniques added to what is now called functional genomics: an interdisciplinary field in which biological questions are addressed by using molecular screening and reagents modulating gene function as a tool. Chemical genomics is a very similar approach; however, it relies on specific small molecules modulating protein function and molecular screening as a research tool. Prior to the development of functional and chemical genomics, it was a *conditio sine qua non* that the protein and its precise function had to be known before a screen for a drug aimed at this target was considered. This has changed to such a degree that screens without a known target are now considered since chemical and functional genomic principles have simplified postscreening target discovery [13, 14]. For example, isolating the target of a small-molecule drug after it has been found in a screen using a genome-wide siRNA collection in the presence of the compound in question is one of many applications for screening as a research tool [15].

On the practical level there has been a transformation of the equipment from expert systems into turn-key systems that are usable to any scientist. Current generations of automation platforms such as liquid handlers have become more and more user/scientist friendly through simplified interfaces and the incorporation of configuration wizards. For example, the early Mini Trak system from Packard was only programmable in scripting language. Since then, a more comfortable graphical user interface (GUI) has been introduced that makes use of these very powerful instruments much easier and enables scientists to be more productive in their research.

## 2 MOLECULAR SCREENING

### 2.1 Low-, Medium-, and High-Throughput Screening and Their Plate Formats

Screening can best be defined for our purposes as the repetitive execution of a given assay in order to find a "hit" compound with a desired biological activity. Consequently, one of the most fundamental properties of any given screen is its throughput, that is, how many compounds or other effectors (siRNA, shRNA, etc.) can be screened per day. There is a general scientific delineation, rather arbitrary in nature but widely accepted, that defines low-throughput screening as up to 1000 compounds per diem, medium-throughput is up to 10,000 compounds per diem, and high-throughput screening as any throughput above 10,000 compounds. The complexity of the assay procedure typically determines the number of wells possible to screen per day. The assay development begins with a full factorial design of the assay. The design will determine the work flow and if any manual labor is necessary. As a rule of thumb, assays that require any form of manual manipulation of the

individual wells will be low-throughput since they have to run in 96-well plates. Medium-throughput assays will run in 384 plates and plate manipulations will be automated, but the assay plates might be moved from workstation to workstation by hand or the assay might run on a fully automated system. Consistent timing of all steps for all plates is the biggest issue in this setting if individual workstations are employed. High-throughput (HT) screening will typically run in 384 or 1536 well plates without manual assistance beyond "feeding the system" or emptying the waste containers.

It is worth having a closer look at the three plate formats and their uses: the 96-well format still has its place for storing larger amounts of compounds samples and in the genomics arena, and the deep-well versions are being used for growing bacteria for the purpose of harvesting plasmid DNA, which can be used for HT transfection. Another application for 96-well plates is organism-based screening—for example, zebrafish-based screening. The main advantage is that its relatively large size can accommodate the space needs for whole-organism-based screens and is accessible for manipulations by hand. Low-volume versions of the 96-well plates exist and have their use in proof of concept experiments. Otherwise the 96-well plates are almost obsolete for screening purposes.

The main workhorse in screening has been the 384-well plate, which still makes the biggest part of all consumables used in screening. Its advantage is its small size—which lends itself to conserving assay reagents compared to 96-well plates—but not so small that it poses any major technical issues in terms of dispensing, plate washing, or reading. It will accommodate a good size number of cells (depending on the size of the cell and incubation time, about 1000–4000 at 50% confluency), and the assay volume can be trimmed from about 15 to 80 μL, depending on the plate subtype used (e.g., regular or low-volume plates). Most plate readers can read 384-well plates at good accuracy and sensitivity. Although evaporation can be an issue, it is generally easily dealt with by (a) minimizing the assay time, (b) using specialty plate lids, or (c) using a good incubator for the plates, which keeps the air at very high humidity or a combination of all the above. Low-volume versions of this plate type are frequently used to save on expensive reagents. Frequently, columns 1 and 24 are not used for experiments as they exhibit evaporation issues.

The 1536-well plates have rapidly become the workhorse of larger pharmaceutical companies [16] since their reduced assay volume (2–8 μL) offers great cost savings, but they suffer from a series of drawbacks. The dispensing and washing process for 1536-well plates requires special equipment. Although there are various plate dispensers for this format commercially available, the quality of those varies considerably from very good to barely acceptable. The lack of reasonably priced plate washers that perform within the very small error ranges permissible for molecular screening makes the general use of the 1536-well format challenging. Another problem with this format is evaporation, which can become rapidly problematic—3- to 4-day assays are usually the longest incubation time reasonable with this plate format. A partial solution is the use of custom lids for the 1536-well plate. Assays that rely on rare cellular events that require the evaluation of a larger number of cells in order to gain usable statistical data will also have issues with the 1536-well format. Furthermore, the signal-to-noise ratio is typically one order of magnitude less than in 384-well plates. Last but not least, it is difficult to preplate reagents such as siRNA's or cDNA containing plasmids in this plate type. These applications are better served in 384-well plates.

### 2.2 Molecular Screening Work Flow

The concept of molecular screening is quite different from performing traditional bench work in the life sciences. Screening is a numbers game and a balancing act. In terms of a numbers game, screening can be compared to playing the lottery, only with buying a lot of the tickets. The chances to win (find a compound with therapeutic properties) increase with the number of tickets bought (compounds screened). In terms of a balancing act, effective screening requires the researcher to balance speed and accuracy. A common challenge for scientists is choosing a process that is neither too slow nor too inaccurate.

Screening is the repetition of an assay (opening the lottery tickets), executed as fast as possible, and winning tickets (hits) are kept and losing tickets (inactive compounds) discarded. Since no assay can achieve perfect results, some winning tickets will be discarded and some losing tickets will be kept—all for the sake of speed or "throughput." However, as long as a sufficient number of the winning tickets are kept, the screen will be a success.

The final consideration in screening is a practical one: In any setting (academic or industrial), the researcher must balance financial constraints (time, resources, and reagents) with the scientific quality of a screening campaign. See Achytuan and Whitten [17] for an introduction to the terminology and concepts needed for the statistical basics needed in development and validation of an assays/screen. First of all, it is important to familiarize yourself with the general layout/work flow of molecular screening. (See Fig. 1.)

At the beginning of the drug discovery process, a strategic decision on a novel target has been made. The

**Figure 1** General work flow of molecular screening.

target could be a protein, a pathway, or even a phenotype. This novel target has been validated to be of high therapeutic and biological relevance and ideally relies on a protein, which falls into one of the classes that are traditionally considered druggable [18]. Experience shows that the majority of current drugs work on G-protein coupled receptors (GPCRs), ion channels, kinases, or proteases. One can argue that the conservative view of drug development, which restricts drug development to those protein classes, is outdated since drug development should encompass novel target classes to respond to novel needs, especially considering the host of novel targets stemming from the human genome project [19]. After selecting the target, the next decision will concern the screening strategy. This could be single-target screening, pathway-specific screening, or black-box approach. Interestingly, all three approaches seem to be equally successful in terms of downstream success [20]. If the screening approach is not target based, the screening platform needs to be selected next. An obvious choice is a mammalian cell system. Other options include screening in bacteria, yeast, or even whole-organism-based screening such as zebrafish.

The screening approach and platform dictate the choice of appropriate assay technology (readouts, reagents, etc.), which is chosen based on its scientific appropriateness, efficiency, and financial considerations. It is absolutely necessary to consider the feasibility of secondary assays/necessary counterscreens and orthogonal readouts at this point, although they are only needed later on. For screens using known pathways or targets, assays for the validation of the hits need to be considered at this point. These assays are vital to the discovery process since they are needed to filter desirable therapeutic compounds from false positives and compounds, which do not have the potential to become a lead due to, for example, their toxicity or lack of specificity.

Together with the assay technology, the assay format has to be determined. Typically, a 384- or 1536-well plate will be used—the 96-well plate is still used when an assay needs to be manipulated by hand or the readout does not miniturize. At this stage small-scale experiments are carried out in order to optimize the assay, test the feasibility of the screen, and confirm the choice of controls and assay format. Next, the validation and screening libraries for this novel target have to be selected.

Validation libraries typically consist of annotated compounds (compounds for which the target and mode of action is known) and other compounds that are known to have activity against a multitude of targets or pathways.

Through the use of compounds that cast a wide net around the biology to be probed, either by directly interacting with the target or by modulating the target through known (or at least conceivable) interactions, the employed assay is subjected to a biological/pharmacological validation. The validation libraries are then employed in order to gain a first indication of the biological/pharmacological behavior of the screen. Validation libraries offer valuable insights into thorny, essential questions, such as whether a given assay has the hoped-for relevance. Potential problems with the small-molecule screening will also become apparent at this stage. At this point the assay is properly configured for the format and the throughput necessary, and plate statistics have validated the assay's accuracy and screening of larger library sets can be executed. A larger-scale screening campaign involves more diverse library sets that cover a broad range of chemical space—this might consist of targeted libraries, a standard set of diverse compounds or a selected part of the compound collection available (smart library).

The data from these large-scale screens is collected and examined for any plate artifacts/trends. The artifacts/trends are removed, the processed data are used to generate a hit list, and the individual hit compounds are then condensed into so-called cherry plates. Secondary assays (i.e., assays that have an orthogonal readout but rely on the same target) and specificity profiling (e.g., on multiple cell lines or homologous proteins) will subsequently indicate the usefulness of the individual hit compounds and aid in flagging false positives. After this point, compounds will either have a known or an unknown target through which they exert their effects. For compounds with unknown targets, target discovery is possible, and potentially novel targets that

are discovered along the way can be fed back into the target discovery cycle. Compounds with a known target and a proper specificity profile can be either advanced into lead discovery or used as novel agonists or antagonists in chemical genomics applications for basic research.

### 2.3 Screening Approaches

***Single-Target Screening*** For genuine single-target screening (on a purified protein or reconstituted pathway) it is necessary to isolate the target. Biochemical assays are the sole method of screening with single targets. Such assays typically contain only the protein in question and substrate or binding partner(s)—and a detection reagent if necessary for the readout. The merits of this approach are simplicity, control over the parameters of the assay itself, ease of use, and speed of the screening process. Since the assay system is simple, the resulting hit compounds can be easily filtered for real and false positives. Additionally, specificity profiling on homologous/related proteins gives an indication of the therapeutic value of a hit compound.

In contrast to target-based screening, assay systems based on cell extracts or cells contain not only the target but also other directly or indirectly related targets that could potentially interact with the primary target in a direct or indirect manner.

A central caveat of target-based screening is that a hit may or may not be relevant in cell-based assays. Compounds that exert an effect on purified proteins may not have the proper membrane permeability to enter the cell or may be overcome by the redundancy of the biological pathway. If a target-based approach is taken, it is essential to establish a cell-based version of the biochemical assay as a secondary screening tool.

***Pathway-Specific Screening*** Pathway-specific screens rely on an assay measuring the functional state of a target pathway. They are by necessity cell based. A typical example for a pathway-specific screen is the use of a reporter gene assay. In this kind of assay, the expression of a reporter gene (e.g., luciferase), which is expressed under the control of the promoter of the target gene in question, is monitored. Therefore, the functional state of the pathway is being gauged using the reporter gene construct. Considering this fact, we can observe that all of the possible targets influencing the functional state of the pathway in question are compromised within the assay system. This works as a multiplier in terms of throughput. Effectively, there it is not only one screen being conducted but many since all the compounds influencing the activity of a reporter will appear as hit. As is self-evident, hits from a screen using this kind of assay can modulate the activity of the reporter gene either directly or indirectly.

Most of the postscreening effort will be directed into looking carefully at questions such as which compounds are direct hits on the target and which compounds obtain their activity by a different means. This type of screen has the potential to deliver more hits than a single target-based screen, which will yield a solution focused only on the target protein(s) and will miss other solutions that might be equally relevant in a more complex pathway screen.

***Black-Box Approach*** The black-box approach is based on a cell-based assay using a phenotype as readout rather than measuring the functional state of a pathway. The advantage is that no a priori knowledge of a target or pathway is necessary. This readout can be very broad—for example, life or death of a cell—in which case it is truly a black-box approach in which no a priori knowledge is assumed or more reduced in scope. For example, it is possible to screen for modulators of nuclear export by tagging the Rev protein, which contains a strong heterologous nuclear export signal (NES), with green fluorescent protein (GFP) in order to make it traceable and track it during the screen using automated microscopy [21]. Such a screen should find compounds that are direct modulators of the nuclear export process but will most likely find as well compounds that have a different mode of action, for example, compounds that are modulators of target gene expression. Generally speaking, in a screen like this, hit compounds may or may not act on the pathway of the target. The obvious downside of the black-box approach is—much like the pathway-specific approach—the lack of knowledge of the mode of action and/or target of the hit compounds.

### 2.4 Cell-Based and Higher-Organism-Based Screening Platforms

***Cell-Based Screening Platforms*** Cell-based assays are frequently but not exclusively based on mammalian cells. For example, nonmammalian cell systems might be necessary for the discovery of antibiotics [22], and yeast can be a great system for heterologous expression of target proteins [23, 24] and thus offer an easily customizable screening platform.

Therefore, cells used in a screen can be prokaryotic or eukaryotic, and each cell-based system will have its own set of necessary precautions. Generally speaking, it is crucial to establish the identity and purity of the cell population before assay development. For bacteria, possible contaminations with bacteriophage come to mind such as M13.[25, 26]. These bacteriophages will not lyse

the cells; instead they will appear to grow at a reduced rate. This can be readily addressed using the top agar method. For yeast things get a little bit more complicated. Contaminations with bacteria—especially *Bacillus cereus*—are a concern. *B. cereus* is very common in the environment and is especially problematic since it is spore forming. It is a close relative of *Bacillus athracis* but has no toxin. The decontamination process is typically long and difficult. Yeast strains contaminated with *B. cereus* are best discarded. Other considerations when screening in yeast-based systems are whether to keep the drug pumps—which are quite active in yeast—intact or knock them out. Both of these approaches have their merit. However, it is necessary to adjust the drug concentration to a higher level for the screen should the drug pumps be kept. On the other hand, the yeast might be less robust if the drug pumps are absent.

For mammalian cells, *Mycoplasma* contamination is one of the most overlooked problems in screens. Tests for *Mycoplasma* are rapid and cheap and there is no excuse for not performing the test before the assay development. Other parameters that are critical are the passage number and the confluency at which the cells are being grown and what confluency they reach during the assay. Generally speaking, the passage number should be small and sufficient backups of the cells should be at hand. The response of the cells in a given assay will most likely diminish with increasing passage number. The same is generally true for confluency of mammalian cells and their response, for example, in reporter gene assays. It is also possible to freeze a large number of cells and use those cells directly in a screen [27].

***Higher-Organism-Based Assays Platforms*** High-throughput screening (HTS) and whole-organism approaches can be combined quite successfully if the organism model fits into the physical dimensions of 96- or 384-well plates. *Caenorhabditis elegans*, *Drosophila*, and zebrafish (embryos) come to mind as suitable organisms for this type of approach, since they are the right size to grow in microformat plates. Zebrafish are notable among vertebrate animals for their production of large numbers of transparent embryos, which makes them more likely candidates for use in the drug discovery process.

The main question as to whether compounds found by zebrafish screening have relevance in mammals remains to be answered. Zebrafish have only been used in drug discovery rather recently, and scientists have yet to develop new clinically viable drugs based on these experiments. However, there is evidence suggesting that some compounds behave very similarly in both humans and zebrafish. For example, Milan et al. reported that 22 out of 23 drugs known to prolong the QT interval (a part of the cardiac cycle) in human prolonged the QT interval in zebrafish as well [28]. Chan et al. reported that a well-characterized antiangiogenic small-molecule PTK787/ZK222584 blocked blood vessel formation in zebrafish [29]. Langheinrich reviews other compounds regulating cholesterol synthesis, coagulation, and vasodilation with analogous effects in both human and zebrafish [30]. It is therefore quite reasonable to conclude that compounds with an activity in conserved biological processes would behave very similarly in human and zebrafish.

Working with zebrafish has several advantages, including an admirable simplicity in terms of procedures performed: the embryos (3–6) are placed in the 96- or 384-well plates and then compounds are added at the usual concentration. Using a microscope or some form of automated imaging system, one can examine the embryos for interesting phenotypes. In addition to being a straightforward process, this sort of whole-organism discovery is also a unique platform for the identification of in vivo modifiers of the wide range of phenotypes present during embryogenesis. By definition, target-based approaches cannot offer this possibility of discovery: The only modifiers identified are those preselected by virtue of offering only one target. This is a compelling advantage for the whole-organism platform, which can enrich our knowledge beyond our ability to anticipate our findings. Whole-organism approaches free us from the limits of our expectations, and they also offer a valuable window into the development process of the embryo. From one embryo, a wealth of morphological data can be gathered by scrutinizing multiple organs, such as skin, hearts, eyes, and brain, at the same time for, for example, angiogenensis [8]. Internal organs can also be examined by issuing tissue-specific GFP transgenic lines. There is a broad context for this data, a physiological framework, offered by the zebrafish as a whole organism. This context excludes compounds with toxic effects at the beginning of screening, which is also quite useful.

## 2.5 Assay Development

Plate-reader-based assays fall into two different categories: gain-of-signal and loss-of-signal assays. Generally speaking, a gain-of-signal screen will deliver more consistent/robust data than a loss-of-signal screen. This holds true for most readout modes with one exception: in the case of fluorescence, gain-of-signal screens will have the added issue of finding fluorescent compounds as hits.

These two are to be differentiated from agonist or antagonist mode screens, which refer to the biological

function of the compounds screened. An agonist is defined as an agent that provokes a reaction, whereas an antagonist is defined as an agent that inhibits a reaction. However, in either case the reaction could be the generation or the loss of signal. Therefore, not all antagonist screens will be loss-of-signal screens and vice versa. Furthermore, screens can be executed in endpoint and kinetic mode. Most screens in HTS are in endpoint mode since throughput is one of the highest priorities, whereas medium- to low-throughput screens—which utilize complicated biological systems—can benefit greatly from kinetic reads. Kinetic reads or data might be collected after the addition of the last component of an enzymatic reaction within several minutes or, for example, every 12 h in a cell-based assay. The advantage of kinetic reads is that the slope rather than the absolute value can be used, and that might come in handy for the elimination of false positives.

Let's examine the main differences between executing an assay in a normal laboratory setting and molecular screening. It will soon become apparent that these differences must be considered carefully, as they will make or break a successful assay for a drug discovery campaign.

First of all, assays are normally performed in singlet, which means that one has only a single chance of catching a bioactive compound. It naturally follows that statistical validation of the prospective assay is a key step. In the ideal case, the validation will be performed on the very machines used in the screening campaign. This saves the later anguish of revalidating an assay on a different set of equipment. Second, all of the plate handling steps during the execution of the assay should be automated, if such automation is at all feasible. In the large majority of cases, each assay step requires the use of a different device, since they all have different capabilities, and for the sake of speed since "double duty" of devices tends to slow the screening process. Each device comes with its own sets of strengths and limitations, which need to be examined in great detail. Each additional step contributes, of course, to the overall likelihood of error. It is therefore quite valuable to streamline the process as much as possible and to limit the number of steps to the absolute minimum. Minimizing the number of steps is also prudent when one considers the logistics of handling large numbers of plates. A large number of plates typically require a fully automated platform and scheduling software in order to keep track of incubation times for each assay step of each plate.

Generally speaking, it is easier to add a liquid to an assay plate, rather than to withdraw the liquid or even to wash the plate. Assays that require only addition steps, steps in which the liquid is added to the assay plate and no separation steps, are considered the easiest to automate and are called "homogenous." We shall now look at the assay development work flow (Fig. 2).

**Figure 2** Work flow for assay development.

***Assay Development Work Flow*** It is very difficult, if not impossible, to give a recipe for successful assay development for screening of therapeutic agents. This is not due to problems with the screening or assay development itself but rather with the disease relevance of the biological target and the model system used for screening. If the target does not have the necessary relevance in the disease, even the best compounds will not make it into drugs since in the latest steps the compounds will fail in the clinical trials—which is extremely expensive. This is outside the control of the screener who cannot—by necessity—be an expert in all disease indications. However, it is possible for the screener to follow a generic work flow for assay development and perform at least a pharmacological validation of the target, which will aid in making sure that the assay has at least the hoped for biological relevance in the model system used.

The steps during the assay development work flow (as summarized in Fig. 2) are: assay conception, proof of concept experiments, validation of the assay on the

automated platform, and pharmacological validation of the assay. Last but not least, we will give a list of the most common error sources. This list is not comprehensive due to the individuality of assays and should be used as a starting point during troubleshooting of an assay rather than a checklist.

*Assay Conception* After a target of therapeutic value has been set, a suitable assay needs to be conceived. The readout for the assay will depend on the selected screening strategy, screening platform, and screening mode. For example, if a gene has been set as a target and the screening strategy has been determined to be a pathway-specific approach, a suitable reporter gene construct could be cloned and cell lines bearing this construct are made. Part of the initial conception of the assay is to determine if the screening approach and the assay are adequate for this target. For example, the reporter gene could be GFP, which would be a fluorescent readout or luciferase, thus generating a luminescent readout. In selecting the readout for the assay, maximal linear range and sensitivity should be emphasized—however, cost can be a major concern as well. Then assay format will be determined for the initial tests and the campaign that is to follow. Other secondary assays should be considered and they should have an orthogonal readout (e.g., using nitroreductase as reporter gene). This is necessary since false positives, which we will discuss later, can be the direct result of the selected readout, which makes it important to have the same assay with a second, independent readout at hand for the rescreening of the hits. Last but not least, counterscreens have to be considered. Typically, these counterscreens eliminate, for example, cytotoxic compounds, which will influence the reporter gene activity by simply killing the cells. Other counterscreens would contain, for example, variations of the promoter in order to get a sense of the specificity profile of the potential hit compounds. During assay conception, reference substances such as known agonists or antagonists as well as siRNAs or shRNAs (or cDNAs) come in handy, as they allow for building a model system consisting of a positive and a negative control even if no reference compounds are available. When conceiving an assay, it is necessary to select from—and frequently experiment with—a multitude of detection platforms and readouts. The two most commonly used assay detection platforms are multimode plate readers and devices for high-content screening. These two platform types have their own sets of advantages and disadvantages, which need to be considered carefully during assay development.

*Plate-Reader-Based Assays* Plate-reader-based assays, generally speaking, rely on one of the five standard readouts, which are fluorescence [31], fluorescence polarization [32], time-resolved fluorescence [33], luminescence [34], and absorbance [35]. The main advantage of plate-reader-based assays is speed, since an entire plate can be read in the matter of minutes, and flexibility, since most plate readers offer many, if not all, of these readouts. Handling the data from these readouts is normally very easy as well. On the minus side, rare cellular events are typically not addressable using plate-reader-based assays since the signal-to-noise ratio is not high enough. Another downside is the generation of false positives, which depends on the reading mode used. We will now discuss the read modes in detail.

Fluorescence intensity is historically one of the earlier readouts for molecular screening. Fluorescent molecules used for screening purposes can be divided into synthetic dyes such as fluoresceine, fluorescent proteins such as GFP [36], and fluorescent inorganic molecules such as lanthanide chelates [33] and quantum dots. All of these classes have their pluses and minuses. Synthetic dyes have their main applications as latent fluorphores, which can be converted by enzymes such as proteases, hydrolases, horseradish peroxidase, and alkaline phosphatase to their fluorescent form. Other applications are the labeling of antibodies for immunostaining. Fluorescent proteins such as cyan fluorescent protein (CFP), GFP, and red fluorescent protein (RFP) are mostly used as reporter genes, with the exception of very bright fluorescent proteins such as, for example, allophycocyanine (APC), which has been used for labeling of secondary antibodies and other detection reagents. The phenomenon of fluorescence energy transfer (FRET) in which the emission spectrum of a donor and excitation wavelength of an acceptor molecule are in close proximity has as well its uses. The acceptor can be another fluorescent dye or just a quencher, which does not emit light but converts the light energy into kinetic energy. In the case of lanthanides the emission response to excitation is much longer lived than in standard dyes or fluorescent proteins. It is in the order of microseconds instead of nanoseconds. Therefore, they have uses in time-resolved fluorescence (TRF): After excitation of the sample, the plate reader waits a given period of time until the emission response of the standard fluorophores is exhausted and then starts measuring the emission of the lanthanides. This reduces the background greatly, leading to a much cleaner signal. Lanthanides can be combined as donors with other acceptor fluorophores to TR-FRET. The lanthanide chelate is chemically easy to modify and, therefore, the system is very useful for measuring the levels of small-molecule analytes such as cyclic guanosine monophosphate (cGMP) [37]. Strongly chelating agents such as ethylenediaminetetraacetic

acid (EDTA) should be especially avoided for lanthanide-based screens as they can possibly strip the lanthanide out of its organic chelator and destroy the detection system. Quantum dots are clusters of inorganic elements that typically are much brighter than traditional dyes or fluorescent proteins, and they exhibit as well an extended emission time allowing for time-resolved applications [38]. Last but not least, excitation with polarized light can be used in order to determine if a fluorophore has been bound by a larger molecule [39]. Small molecules (say, around 1000 Da) tend to rotate very quickly in solution. Therefore, if they are excited by polarized light, they will relax quickly, leading to a reduced anisothrophy, where the emitted light loses its *z* polarization. Larger molecules (e.g., 20,000 Da) do rotate slower; therefore, their emitted light retains the anisotrophy. It follows that the difference in anisothrophy between samples is only big if the difference between molecular weight in bound and unbound states is big. Since kinetic movement of molecules is involved in the measurement principle, it is self-evident that this assay will be strongly dependent on the viscosity of the sample and the temperature at which the assay is run. A difference of 5°C in ambient temperature can be expected to have a considerable effect on the assay results.

As a general precaution it should be mentioned that some fluorophores are strongly dependent on the pH (e.g., fluoresceine); therefore, it is key to check compatibility for the buffer pH and optimal fluorescence performance and, furthermore, some solvents like dimethyl sulfoxide (DMSO) are excellent quenchers of fluorescence themselves.

To complicate matters further, fluorescent compounds (see false positives) can be a problem [31]. This is the case for blue fluorescence, green fluorescence, but not as much for red fluorescence. In my personal experience, in the case of the first two wavelengths about 0.5–1% of all compounds might come up as false positives, whereas in the case of red fluorescence 0.1–0.2% can be expected. Workarounds include the use of kinetic reads instead of endpoint reads. Furthermore, other constituents of assay samples such as phenol red in the cell culture media, some batches of fetal bovine serum (FBS), or bacterial media can be fluorescent and interfere with this readout. In terms of plates, it should be noted that some plastic plates have a much higher background compared with glass bottom plates.

In my own experience, luminescence can now be considered the workhorse of molecular screening [34]. It has basically no background and the sensitivity and linear range are excellent, and in my experience it is more sensitive then fluorescence.

Luminescense has applications as readout for cell viability and reporter gene assays. In the case of cell viability a luminescence mix is added that contains a lysis buffer, firefly luciferase, and luminol but no adenosine 5′-triphosphate (ATP), which is necessary to fuel the reaction. The ATP is supplied from the live cells in the sample and the luminescence signal is proportional to the number of cells—down to about 50 cells per well in an average plate reader. In the case of a reporter gene assay, the luciferase reagent used contains ATP, luciferol, and a lysis reagent but no luciferase, which is supplied by the cells, thus measuring the expression level of the reporter gene.

Assays based on horseradish peroxidase (HRP)—for example, using a secondary antibody labeled with HRP—can be frequently converted to luminescence by using a luminescent substrate. The enhanced sensitivity comes in handy, especially in whole-cell enzyme-linked immunosorbent assay (ELISA) where the expression of a cell surface protein is to be monitored.

Colorimetric or optical-density-based assays are undoubtedly some of the cheapest readouts and therefore very attractive, especially in an academic setting. In an industrial setting, however, colorimetric assays are typically avoided since they can be used for HTS only if the signal difference between negative and positive controls is large enough to be significant in a high-throughput environment—which is rare. The main problem with this readout is that the linear range is very narrow, which is largely a result of the very small path length in a standard 384- or 1536-well plate. Colored compounds can on some occasions be a problem and can be dealt with by taking a baseline read before substrate addition or by using kinetic reads instead of endpoint measurements.

However, measuring optical density (OD) has its definite applications in multiplexing—especially in bacteria-based screens where an $OD_{595}$ reading can be used in order to gain additional information since no reagent has to be added in order to perform this readout.

*High-Content Screening* High-content screening (HCS) is a comparatively novel platform for drug discovery. It has already gained great importance in a short period of time [40, 41]. While plate readers read an entire well (or even plate) at once, in HCS an automated microscope takes one or more pictures for each wavelength of the cells in a given well on a plate. The pictures from one location in a well are then overlaid and automatically evaluated using image analysis software—multiple pictures per well add to the accuracy of the results. A very simple assay would include, for example, a 4′,6-diamidino-2-phenylindole (DAPI) stain for the nucleus—thus enabling the counting of cells—and the

protein of interest tagged with, for example, GPF or RFP in order to follow its fate and score cells as positive or negative. Therefore, high-content-based assays escape the gain of signal/loss of signal classification, which makes them uniquely suited for difficult applications such as functional genomic screens.

It is as well possible to use phase contrast and follow the morphology of the cells. This is technically more challenging since the signal-to-noise ratio is much lower than in fluorescent-based assays and requires more postprocessing, thus adding an additional layer of complexity. The fluorescent-based high-content assays will allow for phenotype-based screens such as translocation assays [21], but still some knowledge of the tagged target protein is required. The phase-contrast-based assay will allow for a true black-box screening. Other applications such as GPCR-based screening are possible as well with the transfluor technology [42, 43].

Since high-content screening is based on the evaluation of pictures of cells, it allows for reading more than one parameter at a time—thus the name high-content screening. HCS has the advantage that toxicity issues of hits will be apparent early on—provided that the data from the high-content screening are analyzed for it [44]. HCS is especially suited for difficult chemical screens with low signal-to-noise ratios. Other applications for HCS are functional genomic screens such as siRNA-, shRNA-, and cDNA-based screens. One of the reasons why HCS is extremely well suited for functional genomics-based screens is that it allows for the resolution of data on a single-cell level. The advantage lies in having the results from each cell as individual data point that can be averaged to a per-well result. This process reduces deviations to a level at which such screens, for which the readout is difficult to monitor or rely on, to a rare cellular event that can be comfortably run. This benefits, of course, the standard screening for NCEs. The other advantage is that it allows for unexpected phenotypes to be recorded (pictures can be analyzed repeatedly), and it does not rely on an assumed knowledge of the mode of action of a target. The disadvantages of HCS are the relatively low throughput—reading can take up to an hour per plate, depending on the system and how many pictures per well are acquired—and the amount of image data that needs to be managed—which necessitates investment into larger computer infrastructure. Furthermore, specialized software is necessary to evaluate the images and configuring the software to score hits correctly may need the help of a biostatistician.

*Proof-of-Concept Experiments* The next step in assay development is to execute small-scale experiments at the bench. The goal is to establish a basic assay using the positive and negative controls, work out basic assay parameters such as reagents, concentrations, and incubation times and the like. This is also the time to explore various assay formats. I typically go directly to 384-well plates as they are still—with a little bit of exercise—amenable to manipulation by hand, but they can be used already for high-throughput screens and it is not such a big step to 1536-well plates after this. It is a good idea to use the detection system (e.g., plate reader and reagent), which would be normally used during the screen, as this saves time, which otherwise is being spent reoptimizing an assay. Here the positive and negative controls are being used in order to explore if a given assay is at all viable. Typically, a $Z'$ value (the formula for $Z'$ is given below) of >0.5 should be obtainable.

*Validation on the Automated Platform* After a low-throughput (manual) assay has been developed and the proof-of-concept experiments have been run, the assay has to be adapted to automation. Since every assay is different, it is difficult to give a general blueprint for assay optimization. However, it is easy to explain what the general direction of optimization is: maximization of the signal-to-noise ratio and minimization of the variance of the signal and noise values. The two main statistical parameters to gauge progress are the standard deviation σ and $Z'$ [45] (see below), however, some people still like to use the signal-to-noise ratio.

$$Z' = 1 - \frac{3(\sigma_- + \sigma_+)}{\left|\overline{\mathrm{CTRL}}_+ - \overline{\mathrm{CTRL}}_-\right|}$$

*In this formula, σ is the standard deviation of either the positive or negative control, CTRL refers to the value for the positive or negative control.*

The basic necessity for an automated assay is a $\sigma^- < 20\%$ and $\sigma^+ < 20\%$ and $Z' > 0.5$. There are as well other statistical parameters that can be used such as $B'$ [46], but I personally prefer $Z'$ during assay development. Especially for loss of signal screens, the σ for the half maximal effective concentration ($EC_{50}$) of a reference compound should be established and needs to be below 20%. An excellent overview of the statistics and procedures for initial assay validation is given in the *Assay Guidance Manual* by Eli Lilly and the National Institutes of Health (NIH) Chemical Genomics Center, version 5.0, 2008. It can be found at http://www.ncgc.nih.gov/guidance/manual_toc.html (last accessed on 9/11/08).

The necessary assay optimization will usually include an optimization of each of the reagents used in a given assay and all steps performed during the execution of the assay. This seems at first somewhat daunting but

becomes very manageable if one parameter is varied at a time.

*Plate Uniformity* Plate uniformity needs to be addressed as one of the key issues for the development of an automated assay. Lack of plate uniformity will make any potentially successful screen impossible.

There are two major kinds of phenomena causing plate uniformity issues: edge effects and plate trends. Edge effect refers to a phenomenon in which the rim of the plate—especially its corners—shows a different signal than the middle of the plate. There are various causes for this and not all are well understood: evaporation on the edges of plates seems to be a major contributor to edge effects since it alters the liquid level at the rim of the plate but not the middle. Consequently, a more concentrated solution found now on the edges of plates can lead to, for example, faster enzymatic reaction. This in turn will increase the signal of a given readout. Or concentrated growth factors in cell culture media will lead to an elevated growth, leading to an increased signal at the edges of the plates. A less understood phenomenon occurs during the plating of cells for a cell-based assay: If a plate is filled with cells in cell culture media and transferred to the incubator immediately, the cells will collect in the corners of the wells at the edge of the plate but will be normally distributed in the center wells of the plate [47]. A workaround is to incubate the plates with the cells for 1–2 h at room temperature before transferring them to the incubator. It is thought that the edge plates warm up after transfer to an incubator at a higher rate than the middle, therefore leading to a different distribution of cells within the wells. This problem will be encountered as well if a cold reagent is being distributed to a plate. The edges warm up faster than the middle leading to a temperature gradient within the plate, which can translate into different enzymatic reaction rates, thus an edge effect. Edge effects are best observed using heat map plots of a given plate.

Plate trends fall into two categories: patterns on a plate or trends in which one side of a plate exhibits a higher signal than the other side. A plate pattern is best detected using a heat map of a plate, whereas plate trends are easily detected using scatter plots in which the data are sorted by row and then column or by column and then row. The reasons for plate patterns can be normally traced back to the impact of individual devices used during the assay run, whereas plate trends are more difficult to trace but frequently are the result of differences during plate incubation. The troubleshooting typically involves taking readings of the assay after each assay step and correlating the occurring signal anomaly with the assay step at which point changes to the protocol can be made. For obvious reasons it is key to run at least one half of plates per condition as the assessment of plate uniformity is one of the major necessities for making a good automated assay and at least one half of plate is necessary in order to detect edge effects.

*Signal Stability and Reproducibility* The assessment of signal stability and reproducibility is vital. This needs to be performed using intraday and interday testing. Sentinel plates, which include only the positive and negative controls and DMSO but no compounds at the beginning, end, and middle of the screen, have great use in this as well.

Automation has the big advantage that a given assay can be run 24/7. This puts reagent stability into the center stage of prescreening validation. All reagents (including cell lines) have to be (a) stable over the entire projected run time of the assay and (b) DMSO compatible. Furthermore, it is imperative to keep a record of all the lot numbers of all consumables—whether this is an in-house produced resource or a commercially available product like plates or detection reagents. The reagent validation needs to be performed for each reagent (and each lot used) separately in order to gain an understanding of the weak points of an assay. Particular care needs to be exerted on validation of reagent storage, which includes validation of freeze–thaw cycles and the validation for mixing different lots of a reagent.

If a given reagent is not stable over the projected run time, it is normally possible to break the run time into smaller parts and use each time a new aliquot of the reagent. This can counter most of the issues of performance degradation at the cost of more manpower. It is interesting to note that reagents tend to degrade in the tubing of liquid dispensers. Therefore, a good way to counter reagent degradation is to back-flush the reagent automatically after each dispense cycle into its chilled reservoir and autoprime it before addition to the next plates.

If the compatibility testing with DMSO—which is normally carried out for up to 4% DMSO final concentration—fails for a given reagent even at 1% DMSO in the final assay buffer composition, the amount of DMSO can be lowered to, for example, 0.1% by using a pin tool set with a smaller volume and higher concentrated compound stocks. However, this will raise the compound consumption since it necessitates having a second deck (i.e., compound collection) and will use more compound during cherry picking since higher concentrated stocks have to be used. Last but not least, it cannot be overemphasized how much the passage number of cells can influence the signal-to-noise ratio.

*Minimization of Steps and Introduction of Breakpoints* Every step in an assay will contribute to its variability. Therefore, it is imperative to simplify the assay as much as possible. For example, two reagents might be added together, thus saving one assay step. It is also necessary to know precisely where breakpoints of a given assay are, that is, points at which an assay can be stopped for any extended period of time without loss in performance.

A good example for simplification by rearranging the order of reagent addition and the introduction of a breakpoint is the use of reverse transfection strategy for screening of siRNAs. For normal transfection experiments, mammalian cells are first grown in a plate, and then the media is removed and replaced with a mixture of siRNA and transfection reagent. Finally, typically after 24–72 h, the plates are read. This work flow necessitates emptying a plate and immediately adding the siRNA/transfection reagent mix using a pipettor. This process is very cumbersome and agonizingly slow if larger sets of siRNAs are to be screened. In reverse transfection, the siRNA solutions are aliquoted into dry plates. This enables one to produce multiple copies of any given siRNA plate set. The aliquoted plates can be frozen and thawed directly before use—thus making it possible to introduce a breakpoint. After thawing of the plates containing siRNA some media is added to resuspend the siRNA, then the transfection reagent is added and finally the cells are dispensed on top: All additions can now be done with a noncontact bulk dispenser, which leads to a vastly improved throughput. The rest of the assay works as in forward transfection strategies. The simple change in the order of reagent addition and the introduction of a breakpoint leads to a 5- to 10-fold increase in throughput.

*Biological/Pharmacological Validation* After the automated assay is established, it is imperative to check if the current assay has the biological relevance hoped for when the original decision was made to pursue this target. The assay development included already known inhibitors—as far as they are available—or possibly siRNAs, cDNAs, or shRNAs. However, this does not protect from surprises, especially if the target is new. A straightforward way to functionally check the biological relevance of a given assay is to run small annotated libraries consisting of a variety of agonists, antagonists of relevant pathways, enzyme inhibitors, ion channels ligands, protease inhibitors, kinase inhibitors, and the like.

The results from this validation screen will indicate whether the assay fits into the biological context expected or if unusual or even abnormal hits are being found—thus making it possible to gain a sense of confidence in the screening results before the actual campaign starts. Furthermore, for novel targets the results from this explorative screen will aid in gaining a better understanding of its basic biology. After the pharmacological validation is complete, the screen can be run against libraries.

*Assay Troubleshooting* When an assay is not performing as envisioned, troubleshooting can be somewhat tricky since many different causes can potentially contribute to poor assay performance. Some causes are plain errors; others just add to the variability of the assay results, thus diminishing the assay performance. Some errors are common, some are specific to biochemical assays, and some are specific in cell-based assays. Common errors are liquid handling errors, reagent adhesion (e.g., peptide adhesion in the tubing of dispensers), insufficient mixing, problems with the incubation conditions, and human error.

Biochemical assays have in addition to the common errors as well solvent effects, reagent stability/solubility, pH, temperature, and the order of reagent additions as potential problems.

Cell-based assays can have all of the above as error sources and as well passage of the number of the cells, cell cycle, confluency, serum/media, cell culture plastics, and infection (e.g., with *Mycoplasma*) as potential problems.

For cell-based assays it should be considered that the biological relevance of an assay system can be a function of time. For example, inflammation can have a direct response that can be measured after 4–6 h or a long-term response that could be measured after 48 h. They are mediated through different pathways but react to the same stimulus. Another related example of this is screening with agonists in an immune background. When looking at short period responses, experiments capture the immediate pathway inductions. At later time points such as 24 h, responses can be convoluted by feedback loops of the stimulated pathways via interferon secretion of the cells in the well.

### 2.6 Library Choices

Molecular screening can be viewed as the interplay between a given assay and the libraries used in screening. Both need to be of high quality in order to deliver compounds with therapeutic value. It would be desirable to match a given assay with the right libraries in order to maximize the chances of successful screening. In practice, this can be very daunting as it is often totally unclear what the best library would be, especially if a black-box approach is used for screening and the molecular target is open. However, having good-quality librar-

ies and sampling as much chemical diversity as possible while using a reasonable count of compounds screened is a reasonable recipe for success [48].

There are various compound types that should be avoided when selecting libraries. A noncomprehensive list can be found in Figure 3. Reviews by Shoichet are a very helpful introduction to the field [49].

There are many different types of libraries to choose from and we will now look at the individual libraries in detail.

***Shortcomings of Compound Libraries from the 1990s and What New High-Quality Compound Libraries Are Doing Better*** Generally speaking, the combination of high-throughput screens and combinatorial chemistry so far has not filled the pipelines in the quantities hoped for—quantities that would be proportional to the compounds screened. This has lead to some disenchantment with molecular screening on the whole [50, 51].

It can be speculated that one of the reasons was—and might still be—poor library quality, and very modest coverage of the chemical space, which had its sources in the limitations of the organic chemistry employed while making these compounds and purity issues of the individual compounds. There are now more high-quality libraries available. Compound purity, which always had been an issue with the first compound libraries that came to market, is being addressed by efforts to use liquid chromatography/mass spectrometry (LC/MS) to purify all compounds going into the screening or at least performing LC/MS on the hits. On the issue of intrinsic quality of the compounds, such as diversity, there has been some progress with diversity-oriented synthesis, which is supposed to mimic natural scaffolds but still be synthesis friendly enough to be used in a combinatorial style. Furthermore, smart libraries are more and more employed. These smart libraries generally try to probe a wide array of scaffolds, searching a wide chemical space, with a minimal number of compounds. Targeted libraries go into the same direction, which now most vendors of compounds offer. These libraries are based on predictive computation and experience in medicinal chemistry, and are skewed toward a given target class, for example, kinases. In reality it cannot be ascertained that these compounds will indeed hit the target class intended, but, generally speaking, these compounds are of much higher quality than the classical, diverse sets that were available before. The newest generation of libraries takes as well toxicological problems into consideration that have traditionally been only considered in phase I and II clinical trials, and anticipates and eliminates these problems from the get-go, thus leading to higher success rates.

***Smart Libraries*** In smart library screening a large chemical space is covered by screening fewer compounds per space unit than normal. The results from screening this diversity sampling set are then used for selecting "smart libraries" around the hit, followed by rescreening of these libraries. Hits from the smart library can then be used in order to generate a small focused subset, that is, smart library, to further refine the location of chemical space screened and expand or "drill down" into the next set of hits. The testing/expansion cycle can be repeated until the best hits have been found.

It appears that large-scale screens are being reduced in their number in favor of smart screens [52]. Some companies have even abandoned large-scale screens altogether, largely because the benefit is not believed to justify the cost and labor involved for these companies. Smart screening strategies have some conceptual problems, however.

One of the main conceptual problems is that smart screening would enrich for false positives as well as real positives. Hits from a smart screen contain real and false positives since every readout type carries its own set of false positives as we have seen above. In order to avoid expanding into the chemical space of the false positives, not only rescreening in the already used assay is necessary before expansion into smart libraries but assays with orthogonal readouts as well are needed to filter the desirable compounds from the undesirables. This means that a screening campaign does not consist of the serial use of one assay for the primary screening and then a few assays for secondary screening but cycling between a single assay and a multitude of assays, which are necessary for filtering, thus slowing down the screening process. Another reason why it is imperative to "filter" for false positives is that chemotypes with undesirable properties tend to have broader structure–activity relationships (SARs)—quite a few of false positives depend on only one structural feature of the molecule—for example, reactive groups such as a Michael acceptor—while compounds specific for the target and thus desirable tend to have narrow SAR. Therefore, without filtering, smart screening could possibly enrich faster for compounds with undesirable properties and a broad SAR than enriching for compounds that have a desirable but narrow SAR.

Another challenge is to determine the number of compounds to screen initially to ensure that the chemical space is adequately represented in the original diversity set. This is very problematic since diversity sets are always selected in reference to a starting point (a single compound). It is unclear at this point how to objectively pick the starting points for the diversity-based sublibraries, which make up the initial diversity set.

**Figure 3** List of chemical moieties with undesirable properties.

In an internal analysis at the Genomics Institute of the Novartis Research Foundation [53], it has been noted that "sampling diversity" is at least for some targets not a suitable approach and that the best compounds might be missed. In this study a retroactive analysis was performed on a larger data set. The initial actual project delivered the usual hit rate and one outstanding hit. For smart-screen purposes, the screened collection set was broken down into small diversity sets followed by iterations with expansions into the initial diversity set. On average, the strategy worked: With only a small subset of the compound deck "screened," it was possible to obtain double the amount of hits found; the screen delivered twice the number of hits found by traditional means. However, the one outstanding hit was missed frequently. Of course, it might be possible to skew the initial diversity set to achieve higher hit rates [54, 55].

Only time will tell whether full deck or smart screening will work best—and this might depend on the target and how amenable the target is to, for example, in silico screening and rational approaches. It can be expected for the foreseeable future that screening large libraries will remain necessary.

***Annotated Libraries*** Annotated libraries play a crucial role in pharmacological assay validation since their use enable the screener to gauge the pharmacological/biological relevance of a given assay system. Various libraries are available. Biomol sells, for example, ion chanel ligand, orphan receptor, enzyme inhibitor, and bioactive lipid libraries. The Library of Pharmacologically Active Compounds (LOPAC) library from Sigma Aldrich is well worth mentioning since it is used very widely [56]. Particular care should be taken that a validation library contains drugs that are specific against certain targets and have a very narrow specificity profile (e.g., certain kinase inhibitors such as the PKA inhibitor HA-89) as well as compounds with broad specificity against a whole target class (e.g., thiol protease inhibitors such as E64). Furthermore, it should be noted that the concentration of the compounds used is very crucial as specificity is a function of concentration: for example, kinase inhibitors can become very promiscuous if used at concentrations much higher than their half maximal inhibitory concentration ($IC_{50}$), which then in turn could lead to wrong conclusions during assay validation. Annotated libraries will, therefore, use each compound in a concentration range, which makes physiological sense.

***FDA Drug Collections*** Every molecular screener's dream is to find a compound directly from a screen that does not need any medicinal chemistry, no absorption, distribution, metabolism, and excretion (ADME) and toxicological (Tox)–Tox issues, no clinical trials, no Food and Drug Admistration (FDA) approval process, and can be used in humans.

At first this seems unrealistic, but, recently, more and more compounds that are already approved find novel uses [57]. There are even some companies that specialize in screening-approved drugs for novel uses. This is very lucrative since the novel use of an already existing drug can be captured in a "use patent," which is not quite as strong as a "composition of matter" patent but does grant the company sufficient time to make profit from their discovery. In terms of libraries, the NIH recently made a collection of compounds that have a history of clinical trial available for a nominal fee (www.nihclinicalcollection.com, last accessed 9/13/08). Other library manufacturers are Prestwick and Microsource who offer libraries containing already approved drugs. In the case of Prestwick, the drugs are off patent, which is especially useful when rapid commercialization is the goal. Another approach is to start with a known drug and develop the side activity into a new scaffold [58]. In this context it is interesting to note that sometimes completely unsuspected activities can be found in already approved drugs. For example, cardioglycosides have been shown to influence splicing at a concentration in the nanomolar range, which is their normal working concentration for cardiotonic uses [59]. Viagra would be another example. Its original use was for hypertension, however, the "side effects" became more lucrative than the originally intended use.

***Natural Products Libraries*** The main attractions of natural products lie in their diversity and typically good biocompatibility. They frequently violate the rule of 5 [60] but still have high oral bioavailability [61]. This might make sense since humans coevolved with these organisms and are therefore adapted to exposure to these compounds. These properties make them ideal candidates for drug leads [62], especially anticancer drugs [63]. However, currently, the most screened compound libraries are of synthetic origin, while about 40% of the approved drugs find their origin in natural products [64]. This disparity was originally due to the greater availability and manufacturability of compounds generated by combinatorial chemistry and the shortened cycle times between testing and synthesizing of analogs in modern molecular screening.

Natural products are more and more reincorporated into the drug discovery process as the bottlenecks for natural product discovery are solved, that is, the generation of libraries and derivatives [50, 62, 65]. Since a big part of the currently approved drugs have their origin in the natural product arena, it should be expected that natural products will add to the rapid population of discovery pipelines with candidate molecules. This is

especially interesting considering that the number of natural products screened was a lot smaller than the number of synthetic compounds screened [66].

Natural product libraries come in various flavors. The compounds can be a crude extract, partially purified—frequently pools of five compounds are being used—or fully purified single compounds. It is imperative to retest or deconvolute the hits from a screen on a natural product library to make sure that the active ingredient is properly identified or to determine the active ingredient. High-throughput LC-MS [67] and high-throughout nuclear magnetic resonance (NMR) [68] are the tools of choice for this process. The main disadvantages of natural products lie in the cost for the compounds and the possibility of discovering already known substances—a problem that can be countered by identifying the active compound very early on—directly after a plate location with activity has been found [22].

Natural compound libraries can be generally classified by the source organism: plant, bacteria, marine organism, fungus, and so on. It has been found that the same plant—just grown in a different climate—can have different compositions; therefore, care is advised. In light of the pharmacological usefulness of the biodiversity on this planet, we would do well in preserving it. As rapidly as species are vanishing, it seems a wise idea to purchase compound libraries for which the supplier either has the donor microorganism or enough material banked for resupply.

***Targeted Compound Sets*** Most compound suppliers offer compound sets that are targeted toward a certain class of proteins or enzymes in an attempt to match an assay or target with the most promising library. This works very well, for example, for proteases in which case peptidomimetics can be used [69, 70]. Another example would be ATP analog libraries for the inhibition of kinases. In this case even some rational design can be performed, with excellent results [71]. It becomes more problematic with targets that are members of a protein class that can bind to a huge array of diverse ligands such as GPCRs where no overall sequence homology is found [72] or ion channels. In both cases the target class is considered highly "druggable," but the ligands bound have considerable variation. For example, in the case of GPCRs the ligands bound can range from lipid derivatives [73] to opoids to muscarinic acetyl-choline [74].

Using a targeted library during screening does not guarantee that a targeted library will hit the class of proteins it is designed to hit. This is even apparent when mining targeted collections for their annotation of some manufacturers: It will be found that the classes have some overlap in their compounds, therefore the "targeting" is hypothetical and the used models do not allow to design a compound ab initio as only targeting a certain class of proteins.

Using these libraries, however, does guarantee that the compound set has been designed in consideration of medicinal chemistry principles, which makes for a high-class compound library. If cost is no objective, one is better off buying only (compounds) made from high-quality medicinal chemistry rather than diverse compound collections that might consist in part of compounds that have not been made with medicinal applications in mind at all. It is nowadays possible to find targeted libraries against most target classes. A noncomprehensive overview of suppliers and libraries is given in Table 1.

***Diverse Compound Sets*** Diverse compound sets as we know them originated from the collection efforts of various compound suppliers after the breakup of the Soviet Union. These collections had an enormous size of over 600,000, even millions of compounds. From these collections, subsets were selected that contained compounds that seemed more or less druglike and its members were more or less well characterized by NMR or LC-MS. These libraries were a boon to the discovery progress of many drug companies as they contained both novel chemistry and very interesting structures. Unfortunately, for quite a few of these compounds resupply was not guaranteed and resynthesis was often not possible due to either missing protocols or the scientists who originally synthesized these compounds could not be found. Other problems included impurities, compounds in different salt forms depending on the batch received, and so on. This ultimately led to much frustration when trying to find out why an active compound became inactive when reordered. Through the feedback of customers these compound collections have been improved and can now be considered fairly reliable sources of screening quality compounds, which can be used to cover a great deal of chemical space—on a budget.

***Library Integrity*** Since the product of molecular screening is basically just a plate number and well coordinated, the continued success depends completely on the quality of the compound in the well that was screened. Therefore, library integrity is crucial to the success of any molecular screening. Almost every person involved in drug discovery can tell anecdotes about the best hits from a screening campaign that turned out to be a very bioactive contaminant in the library screened that could never be identified. A reduction of these contaminants is therefore highly desirable [75–77].

The use of compounds follow a general work flow: First, compounds are selected from compound libraries

using various filters and criterias. Screening compounds typically come in three forms: as loose powder in glass vials, as film in microtiter plates, and as DMSO solution in microtiter plates. These storage forms have different stabilities that need to be considered [78]. If powder was received, it needs to be weighed, dispensed into plates, and dissolved in DMSO.

From these master plates, which are typically at a compound concentration of 10 m*M*, one or more 1 m*M* daughter copies are made. The plates are normally stored under the exclusion of water at +4°C (if DMSO) or −40°C if powder. The active daughter plate is kept at room temperature, if possible under the exclusion of water, and retired after 3–6 months, depending on use. DMSO, which is the best solvent for compounds, is unfortunately extremely hygroscopic, which makes is hard to keep the library integrity high. Left unsealed, DMSO will take up about 30% water [79, 80] at which point the compound solubility is reduced significantly. Furthermore, compounds will decay much faster in the presence of water. The decay process is not well understood, and it is generally difficult to come up with one mechanism since compound collections tend to have up to millions of members that fall into many different scaffolds. It is an advantage to be able to store compounds under inert atmosphere, but water remains the main culprit in loss of library integrity [81].

### 2.7 Postscreening Work and Counterscreens

Recent advances in automation and technology have made the execution of a screen very rapid. Consequently, the size of screened compound collections has grown, putting more emphasis on the postscreening efforts, which consist of data analysis, calculation of hit rates, reconfirmation of hits, counterscreening, dose–response experiments, and specificity profiling of the obtained hits.

***Data Analysis*** Data analysis is a central part of the screening process. Errors are very hard to repair since they typically result in loss of information. Data analysis generally consists of data assessment, correction, and mining (see Fig. 4). The first step in data analysis should be the quality assessment for each plate run during the screen and the sentinel plates, if employed. Since each plate should contain a set of positive and negative controls, a $Z'$ value for each plate can be calculated and plates that might need rescreening can be flagged. The values for $Z'$ and the positive and negative controls can

**Figure 4** General data mining work flow.

be compared over the entire screen and potential problems with, for example, drift of the signal due to signal instability during the screening will become apparent. The next step will be the evaluation of the plate background. The central idea is to check for plate trends and patterns. This can be very difficult work since the background can shift from day to day, reagent batch to reagent batch, or even plate to plate. Makarenov et al. have taken a very elegant approach in using *k*-means partitioning in their HTS corrector package, which allows for automatic assessment of the background and divides the plates into groups with similar background [82–84]. If strong plate trends or patterns are found, their causes need to be investigated before corrective action can be taken. After removal of the background, normalization using the positive and negative controls can be performed for each plate. This can be done as well on a per-screen basis but per plate is most commonly used.

At this point a cutoff needs to be defined in order to select a finite number of hits. Generally speaking, a cutoff that is the sum of three standard deviations plus the average of the control value can be used but, depending on the libraries (e.g., bioactive or focused libraries versus naïve libraries), this might be too much or not high enough. It is simple to experiment with thresholds using a database system or using a graphical representation of the screening data in order to select the cutoff. Useful programs include SpotFire, HTS corrector, GraphPad Prism, and Pipeline Pilot.

At this point it is good practice to examine the hit compounds for SAR series. Most commonly various pharmacophores will be found that have—depending on their moieties they are substituted with—various degrees of efficacy.

The total absence of these SAR clusters should be a strong warning sign that reevaluation of the results is necessary. The emergence of SAR contributes greatly to one's confidence in the screening results. Data from genomics approaches such as siRNA screens require a slightly modified approach toward data mining as the data type generated is different–please see Section 4.1 for details.

***Hit Rate and Reconfirmation*** After the hits are selected, the hit rate can be calculated. The hit rate is the percentage at which compounds are found to score positive during the primary screening. The hit rate is one of the first numbers to be examined directly after completion of a screen as it can give important information on how well the screen went.

A typical hit rate for a naïve library might be between 0.1 and 0.5% for target-based screens and 0.2–1% for cell-based screens. Depending on the assay, screening strategy and the libraries employed, these values fluctuate and sometimes even a hit rate somewhat higher than 1% can be found during cell-based screens.

A hit rate that is significantly higher than 1% indicates either problems with the libraries or the assay system used for screening. On the other hand, a very low hit rate might either indicate that the concentration of the compound is too low or that the target is very difficult to hit, or possibly the wrong type of library has been chosen. As we will see below, in the case of screens that have difficult targets (especially targeted assays) very clean libraries, that is, libraries that do not contain nuisance compounds, tend not to deliver many hits, resulting possibly in a hit rate that is much lower than average [85]. However, the few hits that are found tend to be specific and do normally warrant follow-up. The next step in screening is to consolidate the hit compounds into a custom library and reconfirm their activity in the assay used for screening. The reconfirmation rate is the percentage at which hit compounds that have been identified during primary screening repeat their activity during subsequent tests. Generally speaking, a high reconfirmation rate (>60–80%) indicates a well-functioning screen and a good execution on well-calibrated equipment.

***Evaluating Your Hits: What You Screened for Is What You Get—Precisely*** After reconfirmation of the hits in the original assay, the main question remaining is if hit compounds are doing *only* precisely what was desired or if they have been selected by the screen based on another property the screener is not aware of, and compounds have to be evaluated toward undesirable properties.

At this point it is important to keep in mind that you get what you screen for—if you are aware of what you are screening for or not. For example, a cell-based gain of signal screen for agonists using a reporter gene that is read after 72 h will find the following: agonist of the reporter gene and as well promitotic compounds that simply amplify the number of cells in a given well without changing the expression of the reporter gene. Or an antagonist screen for the same reporter will pick up any compounds which are cytotoxic or inhibitors of the reporter gene protein as well.

***Counterscreening*** It is the purpose of counterscreening to filter the true positive compounds from the false positives. The design of the necessary counterscreens should have been completed during the conception of the assay. Care in the design of the counterscreening strategy is especially necessary where a broader approach such as pathway-based screening or black-box screen has been chosen since not all reasons for false

positives are obvious. Counterscreens have to be designed such that the biological relevance of the hits can be ascertained and false positives can be minimized. Toward this end, counterscreens will generally assess the properties of the hit compounds in regards to, for example, inhibition of the reporter gene protein, activity promiscuity toward other proteins, cytotoxicity, and the like. We will now have a closer look at the reasons why a compound might appear as false positive during screening.

According to Lipinski [85], false positives can be divided into two categories: statistically or chemically caused false positives. Given a $Z' > 0.5$, the number of statistically caused false positives will be very small, since they are the statistical fluctuations or anomalies encountered during screening. Upon retesting, they will be weeded out since these false positives are random, they do not repeat, and have nothing to do with the compounds that were tested in the wells.

Chemically caused false positives, however, do reconfirm: They are caused by a problem related to the compound in the tested well. Compounds of this type are sometimes called nuisance compounds or "frequent hitters" [86] and chemically they fall into at least one of the following classes:

- Reactive compounds—such as reducing agents or covalent modifiers
- Promiscuous aggregators
- Detergents
- Optical interferers
- Cytotoxic or mitogenic agents
- Ion chelators
- Lysosomothrophic agents
- Inhibitors of reporter gene product proteins

It would be a good idea to have a medicinal chemist look through the entire compound deck before purchasing it in order to detect "junk" compounds. Most of these nuisance compounds have in common that they will come up in a multitude of assays. Bioactive compounds will too, but nuisance compounds will come up frequently in biologically unrelated screens, whereas bioactive compounds should exhibit an activity pattern that makes biological sense.

Ridding the panel of hits from nuisance compounds can be time intensive and challenging. General strategies include:

- Inclusion of, for example, detergent in the assay during retesting in order to diminish aggregator activity by scavenging the aggregating compound [87]
- Measuring "compound only" controls in order to detect optical interferers
- Quantifying viable cells per well to determine toxicity or mitogenicity

For dealing with the remaining ion chelators and reactive compounds, an experienced medicinal chemist's help is invaluable.

A further problem is typically the lack of purity of compounds. Even at a compound purity >90%—which is nowadays the industry standard—it is possible that a minor constituent in the compound solution is the active chemotype. This problem will be encountered after reordering compound from the supplier or making a larger, cleaner batch of compound and losing all bioactivity. In order to solve this problem the remaining compound from the library can fractionated by, for example, high-performance liquid chromatography (HPLC); and the active ingredient can be purified before being used in rescreening. Alternatively, all compounds on the deck can be by purified by preparative LC/MS [77]—however, the infrastructure and associated cost can be prohibitive.

A high number of false positives carry a heavy penalty in the labor involved for follow-up work. For every hit compound found, one compound needs to be replated, rescreened in multiple replicates, and if the compound passes the initial reconfirmation, it needs to be characterized.

This has the potential to offset the benefits of walkaway automation of the initial screening, as during the hit characterization the utilized assays tend to become more labor intensive. It is, therefore, crucial to automate the cherry picking and retesting of compounds and confirm the identity of the chemotype in order to keep the labor and possibilities for errors to a minimum.

***Dose–Response Experiments*** After hit confirmation, counterscreening, and confirmation of the chemical identity of the hit compounds, the potency of the hit compounds needs to be determined. The main tasks in potency determination include remaking of the compound stocks, performance of the dilution series, application of the dilution series, and performing of the assays. It should be noted that potency is not the same as efficacy—the first relating to the $IC_{50}$ or $EC_{50}$ and the later relating to the maximal quantity of the response caused by the compound.

Since the compound solvent DMSO is very hygroscopic the precise concentration of the compound in the screening plate set is not really known. Although nondestructive methods for determination of the water content are available [88], it is advisable to go back to compound powder if at all possible and remake the

stocks for potency testing, especially considering possible decay products from the compounds due to extended storage in DMSO. This labor-intensive process can be automated. Dry powder dispensers and automated weighting stations are available from various manufacturers. Alternatively, the purification of the compounds can be automated as well [77, 89]. The new compound stocks are then diluted, which is a simple task using automated liquid handlers. The dilution series can then be applied to the assay plates used for profiling using a pin tool. This strategy has the advantage that it becomes very easy to profile the hits on a larger range of assays without having to remake the dilution series, which saves compound and labor cost. However, it might be necessary to start with higher compound concentrations than the concentrations used during the initial screening, and in rare cases the compounds can stick to the pins. It is generally possible to clean the pin tools very efficiently using a combination of water, DMSO, ethanol, and methanol. An alternative strategy is to pipette the compounds into empty plates and add the assay constituents on top.

The $IC_{50}$ values or $EC_{50}$ values are then evaluated using curve-fitting software such as GraphPad Prism, SpotFire, Pipeline Pilot, CDD, and so on. It is imperative to check the quality of the curve fit, thus making the evaluation of the data a little labor intensive not only in terms of experimental labor but also in terms of data mining. After the dose–response experiments the initially observed SAR clusters of similar compounds should be confirmed and possibly broadened. It is good practice to perform SAR by inventory, that is, rescreen all compounds that are part a given SAR series available in the in-house libraries as well as compound suppliers, even if they appeared to have no effect in the screen.

### 2.8 Specificity Profiling of Compounds

Specificity profiling and mode of action studies are the next step in compound development after dose–response experiments. Compounds can be true positives with good potency and efficacy but still have undesirable secondary properties that render them useless for subsequent development into therapeutics. This goes beyond the concept of counterscreening, which addressed obvious problems such as compounds with frequent hitter profile such as toxic compounds. A major concern is specificity, especially for inhibitors of proteins where a closely related protein(s) has similar activities such as the cathepsins [90–93]. Or, for example, a kinase inhibitor, which has been found to inhibit BCR-ABL in a target-based assay, could still have significant inhibitory potential on the insulin receptor. This does not necessarily come as a surprise given the fact that most kinase inhibitors bind into the active site of the kinase. The active site of kinases is very well conserved since kinases operate using ATP as substrate, and thus the binding pocket is extremely conserved to the point that enables rational design within this pocket [94, 95]. Thus, even for a lead compound that generated from target-based screening the execution of specificity profiling is necessary. This can be fully automated [96]. Furthermore, it is becoming increasingly clear that most effective drugs have more than one target [96, 97], and there is as well more and more evidence from the clinics that certain indications, for example, oncology, require more than one target to be hit.

Another aspect of specificity is the genetic background in which a compound is tested. For example, in the area of oncology it would be desirable to study the compounds on cell lines that have different statuses in all relevant proto-oncogenes. It would be valuable to the drug development program to profile the compounds in a multitude of genetic backgrounds in order to get an understanding of how the compound will act functionally in these backgrounds. The fact that the human genome gains a big portion, if not most of its diversity, by alternative splicing—a process that is far from being wholly understood—makes a functional approach toward hit validation even more appealing [98].

## 3 TARGET DISCOVERY AND HIT VALIDATION FOR NCEs

The main challenge after hits are generated in a particular screen is to find their target(s) and the mode of action. In the specificity profiling examples in the previous chapter (see chapter 2.8), it is very simple since the hit compounds come from a target-based screen. To validate these compounds, one performs basic enzymology tests in order to determine the mode of action and test a panel of the most important kinases and close relatives of the enzyme targeted for off-target activity for biological hit validation. However, one generally does not have this ability with hits that were generated from a reporter gene assay screen or even a black-box screen: These hits were derived from cell-based assays and, therefore, involve a myriad of possible targets and many modes of action.

First of all, it might be a good idea to try to group the hits from a screen into compounds that have structural similarity. Typically, hit grouping will generate a small SAR series around one or more core structures from primary screens. In the ideal case SAR information with

potency and efficacy for each compound is available. Sometimes, single active compounds are found.

Second, these compounds can be combined into pairs. If their effect is cumulative, it is likely that they have different modes of action. The same strategy can be applied by pairing the novel compounds with reference compounds with known modes of action. In both cases knowledge of the $EC/IC_{50}$ values is of great help. Furthermore, secondary biochemical assays that look at phosphorylation states of key proteins (e.g., kinases) in the pathway of interest might give indications if the intended pathway is being affected. It may be necessary to use complicated means in order to assess the mode of action of a given hit such as proteomics, affinity chromatography, or protein microarrays to find the target [99–101]. Some methods will be discussed in greater detail in the following sections.

### 3.1 siRNA-, shRNA-, and cDNA-Based Screens

Loss of function (LOF) screens have recently gained much importance in drug and target discovery [15, 102], and it is to be expected that gain of function (GOF) screens will become equally important if they are not already. Besides the use of small-molecule libraries, LOF screens can be executed using siRNA or shRNA libraries [103]. siRNAs are short synthetic RNA duplexes that inhibit the transcription of their complementary mammalian genes. In the case of shRNA a plasmid containing an insert composed of a sequence that generates a stem-loop RNA driven by a polymerase II promoter can also produce siRNA via processing by Drosha in the nucleus and further processing in the cytoplasm (shRNA). At this time, the synthetic siRNA libraries are readily commercially available since their application in HTS has become routine [104]. A popular utilization strategy for siRNA in HTS is reverse transfection, where siRNA solutions are prespotted into 384-well plates—about 1–2 μL of a 1-μ*M* solution. These plates can then be immediately used or frozen for future use. The next step is the addition of a suitable transfection cocktail containing the transfection reagent and antibiotic and serum-free media in order to both resuspend the siRNA and form complexes. Typical incubation times range from 30 to 60 min. After the incubation time, cells are added in serum containing media. This scheme works extremely well with HEK-293T cells, and Hela cells. The main shortcoming of this system is that it relies on the transfectabillity of the cell line used. Therefore, it would be advisable to design assays based on cells that are compatible with downstream secondary screens using siRNA during the initial planning of the drug discovery campaign. Furthermore, transfection reagents tend to have a cytotoxic character; therefore, they should be removed after the transfection [105]. It should also be expected that the transfection reagent will interact to some degree with the NCE, necessitating additional controls in the secondary assays. Another shortcoming of this system is the transient nature of the gene interference. The amount of siRNA a cell has taken up will decrease over time due to the breakdown of siRNA and doubling of cells. Typically, the maximum time this kind of assay can be run for is about 72 h. If the primary drug screening requires longer incubation times, another technology is necessary. This technology could be, for example, shRNA. The main difference between siRNA and shRNA is that shRNAs can be delivered using a viral vector. This has two major consequences: first of all, shRNA enables—if, for example, a lentiviral vector is being used—the use of hard to transfect cell lines or even primary cell lines. Second, due to the integration of the vector payload into the genome, the resulting cells express the shRNA in a stable manner, that is, the knock-down of a given shRNA over time can be expected to be consistent. Overall, the greatest challenge with siRNA- or shRNA-based screens is the lack of control over how much knock-down of any given gene is being achieved using a single siRNA or shRNA. This is partly addressed in sh/siRNA libraries by having multiple constructs for any given gene. Furthermore, for siRNA, off-target effects have been observed and controls should be conducted before completing hit validation [106]. As a general rule of thumb, at least two constructs that target distinct regions of a given gene need to show activity in order to validate a hit.

Gain of function screens using cDNA in either an expression plasmid, which can be transfected into cells, or in a viral backbone can be used accordingly. Generally speaking, GOF screens tend to give more robust readouts; however, it is expected that gain and loss of function screens will be complementary to each other rather than delivering the same results.

### 3.2 Synthetic Genetic Array

Yeast is a very interesting model organism for compound profiling since many key proteins in human and yeast cells are conserved. Yeast is a unicellular eukaryotic organism that has been studied heavily by geneticists, cell biologist, and biochemists. It is easily altered by exogenous and genomic manipulation and a systematic gene deletion project was completed in 2001 [107]. The assembled library of strains, each with a single, nonessential gene deleted, is commercially available from Invitrogen and has allowed the development of

synthetic genetic array (SGA) screening (reviewed in [108]). Built on the concept of synthetic lethality, SGA screens search for cellular inviabilities that arise only when two or more elements/processes—each of which on its own is nonlethal—in a biological process are impaired at the same time, lethal knockout combinations imply that gene pairs have a related or linked function, for example, in a pathway. [109] Traditional SGA screening in yeast exploits the ability of yeast to propagate efficiently in both a diploid and haploid form. The system consists of a haploid query strain and the arrayed library of haploid yeast, which is crossed in order to generate an arrayed progeny, contain both mutations in the same host.

For compound profiling purposes, one replaces the query strain with the compound in question, and the arrayed library is either plated onto agar or grown in liquid media containing the compound. Observation of synthetic effects of the compound on the members of the library should enable mapping of interactions of the compound with pathways. Of course, an arrayed overexpression library would be attractive for screening in the presence of the compound as well. Such libraries of yeast overexpression plasmids are transformed easily and readily obtainable. A similar approach can be used with libraries of essential genes attenuated through conditional knockouts.

In theory, any colony-forming microorganism can be used with SGA if an array of genetic mutants are arrayed in an ordered system. Most SGA screens use either liquid in microtiter plates, solid support agar, or a combination of both formats. Manual SGA screening using a handheld pin tool is performed in 96-well/colony formats, while automated systems are able to perform in 384, 1536, or higher densities due to their precision manipulation. If pinning operations onto agar are performed, consideration should be given to create "buffer zones" in the outermost rows and columns because of agar wicking around the edge of the plate. Another consideration in SGA is the background of the query strain. The yeast knockout collection is provided in a S288C background, and it is recommended that query strains be generated in this background. Keeping an isogenic background will reduce unforeseen false positives and negatives due to strain variations. Such variation can also reduce strain mating efficiency, an essential component of successful SGA screens. Specialized hardware for SGA screening is offered for Genetix (Qbot, QPix) and Singer instruments. Scoring of "hit" synthetic lethal interactions has been described through automated methods but can also be done by eye [110]. Multiple repeats of the library screen are recommended to improve the accuracy of the results. A high-density screening format can cut consumable costs, screening time, and the physical space required to house the plates.

### 3.3 Affymetrix-Based and Other Chip-Based Assays

Transcription profiling for target discovery of compounds is very rapid and can be very rewarding [111, 112]. Transcriptional profiling relies on the isolation of RNA from a sample treated with the NCE, which is followed by cDNA synthesis during which a dye is incorporated into the cDNA. A second sample, which is treated only with the vector for the NCE is processed in identical manner. This time the cDNA is labeled with a different dye, however. Both samples are adjusted to the same cDNA concentration and hybridized onto an oligonucleotide array containing the sequences of the genome of the organism from which the samples had been derived. After washing to remove unbound cDNA, the arrays are scanned at two wavelenghts to detect cDNAs from the two differently labeled samples. This quantification of the two dyes will allow for ratiometric readouts for every gene represented in the array, thus giving a precise snapshot of the differential expression profile of the untreated versus the sample treated with the NCE. This differential profile should allow for at least an educated guess as to which pathway is being targeted by the NCE. Part of the appeal of this strategy is that various samples can be processed in parallel, so that, for example, multiple cell lines and backgrounds can be examined. The downside of this approach is that only RNA levels are being measured. RNA levels do not account for changes in protein levels or activation or inactivation of a protein by posttranslational modifications. Therefore, this method gives only a crude indication of the actual overall picture of the effects of an NCE. Furthermore, some targets are underrepresented in the transcriptome [113], and the data analysis can be challenging since genomewide data will be acquired and evaluated using this technology platform [114].

Another promising application of the microarray platform is drug profiling with yeast fitness tests. This yeast viability-based system is similar to SGA except that all of the heterozygous deletion strains are pooled into a single culture tube. After addition of a drug, all of the strains simultaneously complete for growth in the culture. Microarrays are used to assess the relative "fitness" of each knockout strain in the drug-containing media. Putative drug target hypotheses can be developed by checking for strains that are vastly over or underrepresented in the culture pool. The idea is that gene deletions that cause hypersensitivity toward a particular drug may be involved with the target of that drug [115, 116].

An interesting combination of microarray and siRNA/cDNA-based technology is the reversely transfected cell microarray (RTCM) technology that relies on spotting of these reagents on a slide and then performing standard reverse transfection. The benefit of this strategy is miniaturization and the possibility of parallel processing of many cell lines. This would enable functional profiling of drug candidates with less cost and effort than non-microarray-based methods [117].

## 4 DATA MANAGEMENT

Without the ability to store, mine, and explore data, molecular screening is unthinkable. Data and data management plays a central role in molecular screening, but little software is available to the public to cross the borders of various system platforms [118, 119]. Most of the tools used in the pharmaceutical industry are written in-house, which means that they are unavailable to the general public. A central role in the process of data mining is data visualization as it allows for the representation of a large set of data without overwhelming the scientist, who then can develop a "feel" for the quality of the screen, if there are any artifacts and the like, just by the appearance of the graphical representation. While data handling and representation is one end of the pipeline, tying these data to structures and managing the inventory of drugs is on the other. Most of the work of connecting data with chemical structures is done using specialized cheminformatics programs such as Accelrys HTS, IDBS, and Pipeline Pilot by cheminformatics specialists. An excellent overview of the products and possibilities is given by Bunin et al. [120]. We will first explore which data types we might encounter and then see what kind of databases we might use to make the most of the knowledge buried in the data.

### 4.1 Data Types

Data come in various forms and sizes in molecular screening. Most data will be generated by plate readers that then consist of one or more numerical values per plate coordinate. The next level of complexity is time-resolved data, such as those generated by fluorometric imaging plate reader (FLIPR) assays. In such an assay all wells of a plate are imaged at the same time with fluorescence values being generated for each time point for each well. One big step up from this situation is image-based data generated by HCS [121, 122]. HCS data can be per-well averages or per-cell measurements. This might include as many as 30 measurements, which are taken from each cell. Per-cell measurements might be biologically the most intriguing kind of data but are very difficult to manage. Furthermore, a database may also contain the original images from the HCS, which complicates the situation further. Depending on the readout, the numerical value will be very different from screen to screen, making it difficult to compare numerical value across different screens. One way around it would be to normalize to positive or negative controls for each screen. Another solution is to remove the background and then divide by the standard deviation—either by plate or by screen. However, dimensionless data might be harder to intuitively understand since the intrinsic biological context of the unit (e.g., percent survival, which ranges from 0 to 100) is missing. However, even if the numerical problem is solved, the challenge of making biological sense of screening data across different screens and screening platforms remains.

Data types can also be divided into data from singlets, one or more replicates, data from pooled compound libraries (i.e., libraries that contain more than one compound per well), and data derived from genomic approaches that contain frequently more than one well targeting a particular gene. Chemical compounds are normally screened in singlet for cost reasons, sometimes compounds are even pooled in order to save money and only active wells are deconvoluted later on. This seems to work reasonably well, even in an industrial setting [20]. Orthogonal pooling strategies, that is, strategies in which a multitude of compounds per well is used, and the deconvolution is already implemented by screening the same compound twice but each time together with different compounds, work as well [123]. In all of these cases, the ranking of the hits is based on activity of the compounds.

Data from genomics approaches, such as siRNA and shRNA, require a different way of evaluating the data. Konig et al. introduced redundant siRNA activity (RSA) analysis [124]. The classical data mining focuses on the activity of a compound. In contrast, RSA analysis takes advantage of the redundancy of the libraries, which often contain two to four sequences targeting one gene. RSA analysis uses all redundant sequences for calculation of the probability for a given gene to be a real positive. In addition, the activity data of the individual wells are weighted into the ranking of the hits. The resulting hit lists lead to higher reconfirmation rates than activity-based analysis alone.

### 4.2 Database Types

Given the number of data points typically collected during screening and the number of compounds these data need to be attached do, data storage in text files or Excel spreadsheets is not an option. The only viable solution is a relational database, which provides built-in

mechanisms for nonredundant data storage and logical associations between various types of data. The two most frequently used database engines are Oracle and MySQL. Oracle is a commercial, "industrial-strength" application, which is a good choice if the database needs advanced interactive features and the ability to be bulletproof even under the most severe circumstances—which is why all top financial institutions use Oracle. Oracle should be installed and maintained by a trained database administrator (DBA), and it is a rather expensive software package. MySQL is an open-source database engine and easier to set up, maintain, and program. It is less expensive than Oracle.

### 4.3 Accessing Data and Integrating Various Platforms for Maximal Efficiency

Before considering which database type the data should be stored in, it makes sense to think about whether to buy a software package for cheminformatics or hire a programmer as this might dictate which database type is necessary. The choice will depend on a variety of considerations such as whether customized applications are necessary or if an off-the-shelf product will perform the tasks needed within the budget available. Frequently, off-the-shelf software is also dependent on a particular database engine and, thereby, imposes specific restrictions on the underlying architecture. Therefore, it is important to evaluate the required feature set and make an informed decision as to which software–database combination to implement. An overview of the products and capabilities is given in Bunin's book and Ling's reviews [119, 120].

In order to answer the question of which kind of database interface to use, the question of who needs to access the data needs to be answered first. Is it a dedicated cheminformatics person or an end user? These two models necessitate different kinds of interfaces/databases. In the first case, an expert system could be used that requires a dedicated person to use it and make data available to the end user. On the other extreme is a system that is easy enough to use for a nonspecialist and enables the scientist to store data, mine, and make use of the infrastructure of the screening laboratory.

The question that stands behind this—is an expert system or a more user-friendly interface employed—is whether a screening laboratory becomes a "full-service" or a "self-service" entity. The advantages of full service, where screens are being dropped off and data are being returned, could be efficiency in the usage of resources. On the other hand, it is to be expected that only a scientist who is very familiar with a given biological system can ensure the best quality of hits from screening campaigns because he knows the biology best. The scientist will notice early on if the system is behaving strangely, for example, if the morphology of the cells is slightly off or similar things that might not be easily quantifiable and therefore difficult to mine for but are early indicators of either success or failure. The model of a visiting scientist works extremely well in my experience.

Frequently, data need to be shared between different locations or collaborators at different institutes. In this particular case, a Web-based interface is a good solution. In my experience, one of the best examples of easy-to-use, Web-based software for data storage and mining is made by Collaborative Drug Discovery (www.collaborativedrug.com, last accessed 9/13/08), which enables scientists who have a minimal knowledge of chemistry to archive, view, and mine their data. A novel trend is to integrate outside database content into internal databases. This is complicated by the fact that there is not one single search engine for this type of problem. While using Pubmed might become a central site for gathering this type of information [125], Chemspider (www.chemspider.com, last accessed 9/13/08) goes the other route. It is a metaengine for finding information on a given molecule in many databases. This search engine scours the Internet for information—like Google. However, it does not use a search phrase but a chemical structure.

As we have seen earlier in this chapter, data from genomic screens require different mining strategies than data from chemical screens. This is further complicated by the fact that compounds are organized by similarity while genomic libraries are organized by gene ontology. Currently, these two data types are normally kept in separate databases. However, accessing data from chemical and genome screens at the same time and integrating the data into one platform will make molecular screening and drug discovery much more efficient. Currently, the means are missing to integrate genomic and chemical screening data. Once cheminformatics and bioinformatics have merged [126], drug discovery will dramatically accelerate.

## 5 CONCLUSION

We have given an introduction to molecular screening, its underlying concepts, work flows, and novel applications as research tool and for target discovery. Molecular screening has changed from a very specialized tool that was primarily used in drug discovery to an indispensable tool for research. The integration of genomic and chemical screening data will lead to a better understanding of disease mechanisms and enable a more efficient drug discovery process.

## ACKNOWLEDGMENTS

I want to thank Etienne Damoiseaux and Dr. Peter Stoilov for proofreading, Sam Hasson for proofreading and his help with the SGA paragraph and figures, Loren Miraglia and Dr. Sasha Buzko for proofreading and many helpful discussions, Tony Orth, Jeff Janes, Achim Brinker, and Barry Bunin for helpful discussions.

# ACCELERATOR MASS SPECTROMETRY AND POSITRON EMISSION TOMOGRAPHY IN HUMAN MICRODOSING

ZHENGDONG CHENG

*Artie McFerrin Department of Chemical Engineering, Professional Program in Biotechnology and Materials Science and Engineering Program, Texas A&M University, College Station, Texas*

## 1 INTRODUCTION

Human microdosing is a novel method that permits improved drug candidate selection by taking the investigational drugs into humans earlier to obtain human metabolism data. In 1991, there was a 40% failure rate associated with inappropriate drug metabolism and pharmacokinetics of candidate drug molecules in the traditional early clinical drug development (phase I) [1, 2]. Over the subsequent decade (1991–2000), attrition for poor pharmacokinetic properties decreased considerably and represented less than 10% of total attribution. More recently, lack of efficacy and/or inadequate safety (clinical or toxicological) have become the primary reasons for attrition [attrition was highest during phase II (62%) but still significant in phase III (45%) and at the time of registration (23%)] [3]. On average, it takes 10–12 years for a molecule from discovery to regulatory approval. The cost of drug development is now greater than $800 million per registered drug [4]. The costs of compounds abandoned during testing were linked to the costs of compounds that obtained marketing approval [5].

There are three main techniques that are used in microdosing studies: AMS (accelerator mass spectrometry), PET (positron emission tomography), and liquid chromatography–tandem mass spectrometry (LC-MS/MS). Both AMS and PET provide much greater sensitivity than LC-MS/MS, allowing the quantification of very low drug levels in plasma after microdosing. However, microdose/AMS or PET studies are labor and resource intensive compared to LC-MS/MS. PET can provide pharmacodynamic (PD) information, whereas AMS provides pharmacokinetic information (PK).

## 2 DEFINITIONS

*ADME* A drug's absorption, distribution, metabolism, and excretion characteristics. A drug's PK and PD define the ADME.

*Human Microdosing* A technique for studying the behavior of a drug candidate in humans through the administration of low dose at levels typically about 100 times lower than the therapeutic dosage predicted from animal in vitro models, and also not exceeding 100 μg, but high enough to evaluate PK properties of the candidate [6, 7]. This technique is also called trace-dose human ADME screening studies, or human phase 0 trials, in contrast to "phase 0 studies" or preclinical studies conducted in animals [8].

*Microdose* A subpharmacological active dose of drug: 1/100th of the projected pharmacologic dose in humans or a maximum of 100 μg [9].

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

*AMS* Accelerator mass spectrometry. AMS is an extension of ordinary MS by including a tandem accelerator to bring ions from tens or hundreds of kilo-electron volts to mgat electron volts of energy, ensuring the efficient removal of molecular isobars and providing the energy needs for other isobar separation [10]. It is a mass spectromic method for quantifying rare isotopes. It has had a great impact in geochronology and archeology and is now being applied in biomedicine. AMS measures radioisotopes such as $^{3}H$, $^{14}C$, $^{26}Al$, $^{36}Cl$, and $^{41}Ca$ with zepto- or attomole sensitivity and high precision and throughput, allowing safe human pharmacokinetic studies involving microgram doses, agents having low bioavailability, or toxicology studies where administered doses must be kept low ($<1\,\mu g\,kg^{-1}$) [11]. It is the enabling technology for human microdosing studies.

*PET* Positron emission tomography. It is a noninvasive nuclear imaging technology that can determine drug distribution and concentration in vivo in humans that utilizes pharmacological or biologically/biochemically active compounds labeled with short-lived positron-emitting radionuclides, such as $^{11}C$, $t_{1/2} = 20.4$ min, $^{18}F$, $t_{1/2} = 109.7$ min. Recent developments in the field of rapid synthesis of organic compounds labeled with positron-emitting radionuclides have allowed a substantial number of new drug candidates to be labeled and potentially used as probes in PET studies. PET microdosing in the drug development process became a method for selection or rejection of compounds based on performance in vivo in humans [12]. Comparing to AMS microdosing, PET offers the key advantage of providing direct quantitative assessment of drug distribution and kinetics in all organs of the human body.

## 3 HUMAN MICRODOSING

### 3.1 Concept

The methods to define the ADME characteristics of a molecule include [8] in silico modeling [13], X-ray crystallography studies of recombinant cytochrome P450s (one of the body's key enzyme systems in metabolizing drugs and foreign compounds) [14], in vitro metabolism studies including the use of animals and human liver microsomes, hepatocytes, or recombinant enzymes [15–17], and in vivo studies using a range of experimental animal models [18, 19]. These studies are used to predict how humans metabolize the drug.

The derivation from animal data to humans is done using a mathematical modeling process known as allometric scaling [20], which is only 60% predictive even though promising ADME data were obtained in animals. Therefore, there is a tremendous need to eliminate this misleading extrapolation of ADME data from animals to dosing in humans. On the other hand, a number of lead candidates might come out of a drug screening program with similar pharmacological activities and identical animal ADME parameters. One has to make the choice which of these leads would make the best drug.

From the middle of the 1990s to the earlier 2000s, research and development (R&D) expenditure has increased almost exponentially year to year, but the number of new molecular entities (NMEs) being registered for marketing is either static or declining [7], even though the number of new molecular entities starting the drug developing process has increased significantly since about 1990 due to the fast progress in biomedical and pharmaceutical research. Figure 1 plots the number of NMEs as a function of time (http://www.fda.gov/cder/rdmt/). There were only 15 NMEs in 2007, the lowest number of launches for 15 years registered by the U.S. Food and Drug Administration (FDA), compared with 36 in 2004 and 53 in 1996. This is an unsustainable situation in need of a fast effective solution. The situation is bad for patients who are looking for new treatments for life-threatening diseases such as cancer, and bad for the pharmaceutical industry who will generate insufficient profits to develop the drugs of tomorrow [21].

In *the traditional paradigm for drug development*, as illustrated in Figure 2A [8], upon the identification of an interesting compound, selected from animal and/or in vitro data, an investment is made into the development of a scaled-up synthetic process for a pilot plant synthesis of up to 10 kg of the drug substance. This substance is extensively characterized and used to assess

**Figure 1** NMEs registered by U.S. FDA.

**Figure 2** Schematic of conventional and microdose approaches to drug selection [8]: (A) Path for a conventional phase I development program. The time taken to obtain human PK data for one new chemical entity can be up to 18 months. (B) Development path for a microdosing development program. Several new chemical entities can be taken through the program and human PK data obtained within 4 months.

safety issues through the conduct of 2- or 4-week toxicology studies in the rodent and nonrodent as well as gene toxicology and safety pharmacology studies. In addition, significant investment is made in the area of drug metabolism and in pharmaceutical development for the elaboration of a suitable delivery system for the compound. The time required for these activities to a first dose in humans is very compound and company dependent but typically would be 1.5–2 years.

The low success rate for drug development has been ascribed to the high number of new molecular entities with diverse mechanisms of action (MOA) to be tested for activity and efficacy combined with the lack of predictive preclinical models and inadequate

and complex clinical trial designs [22]. Overall 75% of the costs of drug development is associated with failures, mainly in the early stages of development. Often the toxicity is severe and poorly predictable. Furthermore, 40% of exits from phase I trials are caused by inappropriate pharmacokinetics of the test compound [1]. Several investigational new drugs fail in clinical testing because they do not behave pharmacologically as predicted in animal studies. Consequently, there is a need for additional methods to evaluate potential new drugs and to optimize existing development strategies.

In 2004, the U.S. FDA Critical Path Initiative [23], as well as the European Medicines Agency Road Map to 2010 [24], declared the urgent need for new toolkits to improve the critical development path that leads from scientific discovery to the patient [9]. In this scenario, *Phase 0* (zero) *trials* (or *human microdosing studies*) should allow an early evaluation in humans of pharmacokinetic and pharmacodynamic profiles of test compounds through administration of subpharmacological doses and for a short time period to a low number of humans (Fig. 2B). Typically, phase 0 studies have no therapeutic or diagnostic intent. Owing to the low doses administered and the low risk of toxicity, shorter preclinical packages to support these studies are required. Phase 0 trials have been proposed to help in making an early selection of promising candidates for further evaluation in phases I–III trials, providing a potentially useful instrument for drug discovery, particularly in the field of oncology. Phase 0 studies are expected to reduce costs of drug development, and to limit the preclinical in vitro and in vivo testing and the time period of drug development.

It is noteworthy that (a) a minimal toxicology package is required prior to a microdose study and hence only laboratory-scale quantities of drug substance are required, (b) the timelines to conduct a microdose study from commencement of the toxicology to obtaining human PK data are between 4 and 6 months in contrast to phase I study timelines of 12–18 months and (c) the costs of conducting a microdose study program are substantially less than a full phase I study program [25].

Human microdosing is a concept in line with the so-called translational science [26–29], the development of new concepts and tools that may provide more confidence in the selection of drug candidates early in clinical development. The process of discovery of new drugs and their full evaluation in the patients for whom they are designed involves at least five crucial extrapolations: (1) from physicochemical properties to biology (structure–activity relationships), (2) from in vitro to in vivo (within animal species and within humans), (3) from animals to healthy human volunteers (phase I—human safety and pharmacological proof of concept studies), (4) from single doses to multiple doses, and (5) from healthy volunteers to patients (including pathology and drug interaction considerations). Of these, the extrapolation from animals to humans is probably the most significant one. This step is now viewed as a critical component of translational science, which potentially embraces four of the five extrapolations listed above, excluding only the structure–activity relationships. Several nontraditional approaches are available to obtain an early assessment of pharmacokinetics and pharmacodynamics in first-in-human studies. Under the right circumstances, these methods may help early drug development decisions to be made more efficiently. Microdose studies are one of those approaches, but they will allow only assessment of pharmacokinetic properties [3].

### 3.2 Applications

The steps before human microdosing involve (Fig. 2B) identifying one or more drug candidates with high affinity to the target protein and demonstrating pharmacological activity in in vitro and animal models, conducting limited animal safety testing, and chemically synthesizing the appropriate isotopically labeled drug molecule [8].

In human phase 0 or microdosing studies, trace amount, subparmacological does of drugs are administrated to human subjects to obtain basic PK parameters such as clearance, volume of distribution, and $t_{1/2}$. An intravenous (IV) dose is often very useful, even for drugs that are intended purely for oral administration. (Because a drug achieves very low plasma concentrations after oral microdosing, the IV dose might show it is due to an unexpectedly high volume of distribution instead of lack of absorption.) Microdosing depends on the availability of ultrasensitive analytical methods, such as AMS and PET, that are able to measure drug and metabolite concentrations in the low pictogram to femotgram range. AMS is used for determining PK data by taking body samples over time, processing the samples in the laboratory and then analyzing their drug content. PET provides primarily PD data through real-time imaging and some limited PK data. In the latter technique PK data can be obtained for only some 2 h after drug administration (i.e., six decay half-lives), while PK data can be obtained using AMS for up to 100 days after drug administration [25]. The new path outlined in Figure 2B contrasts with the traditional approach (Fig. 2A), in that early in vivo human metabolism data make a key contribution to candidate selection. The information from microdose studies can be fed into in silico PK models to obtain a much better

estimate of the likely pharmacological dose in future efficacy studies [8].

Human microdosings, or phase 0 trials, are clinical studies conducted early in phase I, before the traditional dose escalation, safety, and tolerance studies. These first-in-human trials should involve a very limited number of normal volunteers or patients, exposed to a novel compound at a reduced dose compared to starting doses in phase I and for a short time period. Phase 0 clinical trials have no therapeutic or diagnostic purpose for the volunteer; in principle, they should allow researchers to quickly establish whether a novel compound has appropriate pharmacokinetic and pharmacodynamic profiles in humans. Phase 0 trials will not replace the traditional dose escalation, safety, and tolerance studies, and they will not indicate whether a candidate drug has a positive impact on the targeted disease. However, owing to the low doses administered, the limited number of humans treated and the reduced risk of toxicity, the phase 0 strategy would require fewer preclinical in vitro and in vivo studies than a typical phase I trial and a reduced amount of the experimental drug. Potentially, phase 0 clinical studies could help in eliminating candidate drugs before they reach phase I testing, thus reducing costs and time and improving the efficiency of drug development [22].

***Phase 0 Infrastructure*** The development and conduct of phase 0 trials requires a smoothly integrated infrastructure with a collaborative and highly motivated multidisciplinary team of professionals. Phase 0 trials provide an opportunity to establish feasibility and qualify assay methodology in limited numbers of human samples before embarking on studies that involve larger numbers of patients receiving higher, potentially toxic, doses. Phase 0 trials require the rigorous development of assays for target modulation and pharmacokinetic analysis before the initiation of the clinical trial, and real-time analysis of patient samples during the conduct of the study. This raises certain unique logistical, ethical, and statistical considerations, in addition to the intricacies of the required pharmacodynamic and pharmacokinetic studies that need to be carefully planned and managed before and during the conduct of phase 0 trials [30].

Microdosing can be used in a number of ways:

*1. Comparative Human Microdose Study* It aims to establish human PK for a number of molecules that are identified with good pharmacological activity but similar or different animal PK [25]. The obtained human PK data can be used to (a) assist in the drug candidate selection process, (b) determine the first dose for the subsequent phase I study on the selected candidate, (c) establish the likely pharmacological dose, and (d) calculate the likely cost of goods. This parallel way of conducting microdose studies is most appropriate when several drug candidates are available, perhaps with a common structural core where the radiolabel can be introduced into the core portion of the molecule. These parallel studies are best conducted on between two and five molecules using parallel human subject groups. Each molecule might be administered in a crossover design such as an intravenous dose followed after a suitable washout period with an oral dose. Thus, $V_d$ (volume of distribution) and CL (clearance) can be obtained as well as the other standard PK parameters.

*2. Iterative Microdosing Study Performed Compound by Compound* [25] Through each microdosing round, the PK and bioavailability properties of the molecule can be improved to, in the end, provide a molecule with the optimal desired PK properties. In one such study, three molecules were examined in sequence; with each microdosing round the systemic bioavailability was raised from a base value of 10% to a value of 80% in the third molecule. This iterative sequence was conducted in the space of 12 months, including the radiosynthesis, toxicology, clinical study, and bioanalysis.

*3. Microdosing with a Single Molecule* In some cases, the drug discovery process might only yield a single molecule. Microdosing can still be useful in such circumstances as it can quickly establish if it is worth taking the molecule forward prior to committing large-scale resources to a full phase I study. Sometimes a metabolic pathway is identified in human hepatocytes or liver microsomes, which is not seen in animals. Microdosing can be used to establish if the pathway occurs in vivo [25].

*4. Ensure Human Pharmacokinetics* For a *compound* in a precedent therapeutic area for which the target pharmacokinetic profile is known reasonably well, but prior data from related compounds indicate that there is too much *uncertainty in the prediction of human pharmacokinetics* [3]. This has been a rationale for a number of microdose studies at Pfizer.

*5. Applications beyond Drug Candidate Selection* Microdosing has been widely used to obtain phenotypic information on enzyme or transporter activity, for example, with the administration of small doses of erythromycin or midazolam to assess an individual's cytochrome P450 3A4 activity [31].

The current availability of advanced analytic equipment that permits detection of low concentrations of a drug in human matrices also enables microdosing to be

used in the application of previously unfeasible study designs in oncology and unanswerable questions to be investigated experimentally [32]. AMS microdosing provides a unique opportunity to revisit and reevaluate the drug interaction potential of imatinib at steady state. Microdosing should become an integrated approach to human studies aimed at *understanding* basic pharmacokinetic properties of (approved) oncology drugs that require continuous dosing. Another currently unexplored opportunity is the utility of microdosing to evaluate the contribution of germ-line variants in genes with a confirmed or suspected role in the pharmacokinetics of oncology drugs [32]. It is anticipated that in the near future microdosing will make a significant contribution in determining the relative role of genetic variation and environmental factors in the absorption and disposition of a wide variety of agents.

### 3.3 Pros and Cons of Human Microdosing

The database for microdosing studies is very small right now. It might take time to recognize its potential benefits and to be adopted. However, the adoption is accelerating, and the regulatory climate in Europe and the United States has changed, permitting microdose studies to be conducted with a minimal toxicology package. Small to medium size biotech companies are conducting microdose studies earlier than big pharma, perhaps reflecting a greater willingness to adopt innovative approaches by these scientist-led organizations [25].

The phase 0 trials were designed to improve the drug development pathway [22]. Phase 0 trials may shorten time periods to first-in-human studies through an earlier evaluation of human pharmacology of a test substance. The big advantage of phase 0 trials is the possibility to explore PK and PD profiles of candidate drugs in humans (such as bioavailability, metabolism, tissue distribution), thus potentially helping in the early selection of promising compounds for further development before traditional phase I trials. Indeed, one of the major limitations in anticancer drug development is the poor correlation between preclinical and clinical PK and PD. The early evaluation in humans of the candidate drug could potentially help in accelerating the selection of promising compounds, thus increasing the efficiency of the drug development process. For an example, the bioreductive agent EO9 was developed in phase I; however, its pharmacokinetics in plasma showed extensive and rapid degradation to inactive metabolites, making the drug unsuitable for intravenous application [33]. The time-consuming and costly phase I study could have been prevented if a phase 0 study had have been performed. In addition, inactive treatment of patients who took part in that study could have been more limited. Considering the reduced risk of human toxicity owing to the low dose of the test drug administered and the short time period of drug exposure in phase 0 trials, the preclinical safety packages, animal use, amount of test drug, development time, and costs will be reduced [22].

The potential disadvantages of phase 0 studies are:

***1. Radiolabeling Difficulties*** Radiotracer PET assay has the disadvantages of short tracer half-lives and limited specificity (assay may include metabolites). For both PET and AMS, drugs must be labeled at metabolically stable sites [25]. The use of lower doses than of traditional anticancer agents, thus potentially creating significant problems regarding the bioanalytical techniques, especially when there are few validated biomarkers for predicting anticancer activity. Pharmacological, biological, or imaging measurements at very low exposure levels are required, but unfortunately few reliable and validated assays are currently available even for most approved targeted cancer drugs. Moreover, along with novel therapeutic targets, more potent anticancer molecules have been discovered recently.

***2. Time Delay Concern*** Phase 0 trials may get drugs faster into the clinic, but there are still concerns *whether they can significantly shorten the drug development process*, as they will not replace the traditional dose escalation, safety, tolerance, and efficacy studies. The value of obtaining human data earlier, with fewer resources, must be weighed against a program delay to complete additional preclinical work and file a traditional investigational new drug (IND) application if a compound is found suitable for further development. The probability of success based on prior information from related compounds is an important factor to consider. If that probability is relatively high, a traditional phase I clinical program probably provides the most expedient path forward for that compound. However, it is also important to consider the benefits in terms of the portfolio of compounds because nontraditional approaches may cause a delay in one program but benefit the overall portfolio strategy by allowing more compounds and mechanisms to be evaluated for a given amount of resources. Finally, it is essential to be willing to make "go/no-go" decisions based on the relatively limited data from the various nontraditional approaches [3].

***3. Ethical Considerations*** Other limitations relate to the lack of therapeutic intent of phase 0 trials. The lack of therapeutic benefit is justified by the risk for the patient that is clearly less in a single-dose phase 0 trial

than in a standard dose-escalation phase I study. However, in phase I trials, although developed without therapeutic intent, there is on average a low response rate of about 5% [34], whereas in phase 0 trials *no therapeutic gain can be expected*. Therefore, besides the ethical issue, the motivation of patients to participate in a phase 0 trial may significantly affect the success rate of these trials. Similar to several phase I studies, in phase 0 trials, serial tumor biopsies may need to be obtained or other invasive procedures may be necessary. Invasive procedures can be justified by the fact that more effort should be undertaken to develop decisive pharmacodynamic assays. However, it is difficult to envisage that an end-stage patient will consider to undergo multiple hospital admissions, multiple PK samplings, and serial tumor biopsies without any potential benefit. If safe enough, the evaluation of the pharmacokinetics of a drug candidate can be conducted in healthy volunteers; however, PD measurements in tumor tissues and studies with cytotoxic agents have to be evaluated in patients.

***4. Subject Recruiting*** Participation in a phase 0 trial might delay or exclude the patient from other clinical trials that may have some, although little, therapeutic intent. Although the total duration of a patient's participation in a phase 0 trial is short and is expected to last no longer than 1 week, not only the preparation for a subsequent clinical study may be delayed but also a wash-out period may need to be taken into consideration. These issues may significantly impair patient recruitment, thus influencing the feasibility of phase 0 trials.

***5. Pharmacodynamic Considerations*** A fundamental question concerning microdosing is whether there is a correlation between metabolism at a microdose and a pharmacological dose [25]. The U.S. FDA 2006 guidance states that microdose studies should be utilized in oncology, primarily for imaging endpoints. However, as intended by the European Medicines Agency's (EMEA's) position paper, microdose studies could be used to evaluate human plasma pharmacokinetics and/or distribution properties or the receptor selectivity profile of new drug candidates [35]. In this case, an important question is whether there is a good correlation between the pharmacokinetics of a microdose and of a therapeutically relevant dose. In a study conducted by the Consortium for Resourcing and Evaluating AMS Microdosing, five drugs for which it was difficult to predict human pharmacokinetics were administered to subjects at a microdose and at a therapeutic dose level [36]. Of the five drugs evaluated, microdose measurements predicted the pharmacokinetics of three compounds well when administered at therapeutic levels and gave important metabolism data for one drug. An approximately 70% correspondence between the pharmacokinetics of a microdose and of a pharmacologically relevant dose was found. Microdosing appears to be appropriate for compounds (e.g., small organic molecules, peptide and protein therapeutics) with linear pharmacokinetics, small molecules with short half-lives or compounds that are metabolized and that have a rapid dissociation of binding to their target. In contrast, microdosing was not predictive for molecules with nonlinear pharmacokinetics and/or with high-affinity binding to their targets [7, 8, 36–38]. A microdose may not predict the behavior of clinical doses, although we have a body of evidence that for many drugs linearity or near-linearity is approached [25].

In summary, human microdosing studies are most valuable if (1) the obtainment of pharmacokinetic information is important, and (2) microdosing gives better prediction than traditional methods [39].

### 3.4 Short History of Microdorsing

***1. Radioactive Drug Research Committee*** Since 1975 the FDA has allowed basic clinical Critical Path Initiative research involving radiolabeled drugs at microdose, or subpharmacologic levels, to be conducted without an FDA investigational new drug (IND) application. Although the concept of "microdosing" has only been introduced in 2004, this program, codified in 21 Code of Federal Regulations (CFR) Part 361.1 established a process by which a medical institution can conduct such research under an FDA-approved Radioactive Drug Research Committee (RDRC). The program's intent was to encourage basic human research. Currently, there are 83 committees overseeing such research in the United States. RDRC research is considered basic science research. This research is intended to obtain basic information regarding the metabolism (including kinetics, distribution, dosimetry, and localization) of a radioactive drug. It is *not* intended for therapeutic, diagnostic, or preventive benefit to the research subject, and is *not* intended to determine the safety and effectiveness of the drug. Such types of investigations would require an IND. RDRC research must be conducted in a facility licensed for the use of radioactive materials in humans and conducted by qualified study investigators. The research protocols must be approved by the associated institutional review board (IRB). Research subjects must be properly selected, informed, and any adverse events must be reported to the FDA. Quality assurance testing of the radioactive drugs must be performed, the pharmacologic dose of the radioactive drug to be administered must be low enough to not cause any clinically detectable pharmacologic effect in

humans, and specified organ and whole-body radiation dose limits must not be exceeded.

FDA's RDRC program has been allowing microdosing study since 1975, with certain restrictions. Research is not allowed on new molecular entities (NMEs), there must be "no clinically detectable pharmacologic effect," and radiation doses to the whole body and specific organs may not exceed certain limits. Elements of new initiatives to improve human research on drug development, such as FDA's Critical Path Initiative and Microdosing, can be seen in FDA's RDRC program. This program relies on a local committee of qualified experts to provide the necessary oversight to conduct such basic human research safely.

***2. EMA Microdosing 2004 Paradigm*** A new paradigm for first-in-human studies in drug development where compounds could be investigated more efficiently for their pharmacokinetic profile emerged as the *microdose* European Medicines Agency (EMA) position paper in 2004 [39]. Toxicology testing limited to the rodent as extended single-dose studies (via the IV route and the intended clinical route *as well as* gene toxicology and safety pharmacology studies) allowed entry into humans with a laboratory batch of drug substance.

***3. U.S. FDA expIND 2006 Guidance*** The next evolution of exploratory studies in humans, at least by a health authority guidance, was the publication of the FDA exploratory investigational new drugs (expIND) guidance in January, 2006 [40], which was linked to the Critical Path Initiative [23]. The aim of the guidance, developed by the Center for Drug Evaluation and Research (CDER) (2006), was to "clarify what preclinical and clinical approaches, as well as chemistry, manufacturing and controls information, should be considered when planning exploratory studies in humans, including studies of closely related drugs or therapeutic biological products, under an investigational new drug application" [22]. This document was guidance on how the IND process could be used with more flexibility illustrated by providing three examples, implicating that the FDA would consider a unique preclinical program for exploratory INDs. The first example in the guidance addressed microdosing. The concept evolved significantly from the EMA guidance in that *only the route intended for the clinical study needed to be used* in an extended single-dose rodent toxicology program and *no* gene toxicology or safety pharmacology data were required.

The second example accurately reflected a proposal made to the FDA by the Pharmaceutical Research and Manufacturers of America (PhRMA), the U.S. pharmaceutical trade association, illustrating the study of pharmacologically relevant doses [22]. They are aimed at exploring pharmacologic effects of a test molecule. These phase 0 studies have no therapeutic or diagnostic purpose and are not meant to evaluate the maximally tolerated dose. The support of *a preclinical safety package* is more extensive than that of microdose studies, but still less than is required for traditional phase I IND studies. The paradigm allowed entry into humans based on a full 2-week good laboratory practice (GLP) compliant rodent toxicology study in both genders as well as a nonrodent study in a very limited number of animals dosed at one dose level (the no-adverse-effect level (NOAEL) of the rodent study extrapolated based on body surface area) for the intended duration of the human trial. Dosing in humans is limited with a start dose criterion (one-fifty of the rodent NOAEL study extrapolated on body surface area) as well as stop dose criteria based on the dose and exposure observed in the toxicology program—one-fourth of the rodent NOAEL dose extrapolated by body surface area, one-half the exposure [area under the blood level curve (AUC)] at that same dose or the exposure (AUC) observed in the nonrodent study. Multiple-dose studies in humans were limited to 7 days. The filing is a single administrative procedure allowing more than one compound and protocol. This paradigm has been successfully employed by the industry since the issuance of the guidance for >25 INDs up to early 2008 [9].

The third example of clinical studies of MOAs are related to efficacy. They are designed to evaluate the pharmacodynamic effect of a new drug that is expected to be correlated with its clinical activity. Typically, these phase 0 trials present biomolecular endpoints, such as the rate of an enzyme inhibition or the degree of saturation of a receptor. These clinical studies of MOAs related to efficacy have been proposed as particularly useful in the oncology field for the evaluation of molecularly targeted anticancer agents. Indeed, according to the guidance, based on careful preclinical studies and appropriate assay development, a single dose of a targeted agent can be delivered with minimal risk (since such agents have been developed for chronic administration) at a level that has the potential to have a pharmacodynamic effect in tumor tissues in patients. This is expected to speed up drug development timelines by early evaluation of target effects and the usefulness of the assay systems for such targets [22].

***4. Belgian Health Authority 2007 Guidance for Exploratory Studies in Humans*** It was posted at the Belgian health authority website in June 2007 [41]. This national guidance incorporated the US F.D.A. 2006 guidance in terms of the first two examples with some changes.

On March 13, 2006, six healthy young volunteers took part in a clinical trial in London and became violently ill minutes after having been injected with the drug TGN1412 developed to fight autoimmune disease and leukemia. This case demonstrates that even those animals claimed to be the "best" models give false reassurance regarding human safety. TGN1412 had been tested in both rats and monkeys. The drug company (TeGenero, based in Würzburg, Germany) had mistakenly assumed that tests in monkeys would predict human reactions due to the fact that the antibody reacted with both its human target protein and a similar protein in cynomolgus monkey cells. But despite the fact that the human doses were 500 times smaller than in the primate tests, a catastrophic chain reaction occurred in the human volunteers that was entirely unanticipated by the monkey tests [42, 43].

As a direct consequence of the TGN1412 episode, a new paradigm evolved for setting the first dose in humans assuring that the dose would be below the minimum anticipated biological effect level (MABEL) [9]. MABEL is to be assessed from all appropriate preclinical data extrapolated to humans. In addition to the rat NOAEL start dose criterion, the Belgian 2007 guidance includes *the MABEL principle*. The second change from the U.S. FDA 2006 guidance allowed dosing in humans up to 2 full weeks. Provisions were made to allow dose escalation in humans above the FDA stop dose criteria (translated to focus solely on exposure and not the rodent NOAEL dose). Escalation could proceed if the toxicology of the substance was of a non-life-threatening nature and was monitorable. Third, the guidance also offered a new paradigm, which had been evolving through European Federation of Pharmaceutial Industries, the European trade association. It allowed entry into humans based on GLP-compliant 2-week rodent and nonrodent studies where the top dose in each species was capped at an exposure level 10-fold higher than the exposure desired in the clinical program. This *capping of the upper dose* offered the advantage of being able to predict compound requirements accurately for the complete early development program, a significant savings to the industry. In addition, if target organ toxicity was observed in either or both species, an opportunity was offered to move directly into a classical phase I program. This paradigm has yet to be used by the industry [9].

The fourth change in the Belgian 2007 National Guidance from the U.S. FDA 2006 guidance was in the area of microdosing. It allows the microdose to be given in divided doses and also allows for 100-μg doses to be given up to five times as separate doses with an appropriate washout period between doses. This latter approach requires a 7-day GLP rodent study to support it. These microdosing changes are considered to be an important step forward for imaging studies.

This is a single administrative procedure for more than one compound and protocol and Belgium has received four exploratory clinical trial applications (expCTAs) up to early 2008 [9].

## 4 ACCELERATOR MASS SPECTROMETRY

### 4.1 Short History of AMS

***Beginnings of Accelerator Mass Spectrometry*** Although its use in 1939 helped the discovery of $^{3}$He in helim at natural abundances by Alvarez and Cornog [44, 45], AMS was normally considered to emerge from low-energy nuclear physics laboratories until the late 1970s in the unsuccessful attempts made to ascertain the $^{14}$C/$^{12}$C ratio by conventional mass spectrometry [46]. Its development was driven by a need to radiocarbon-date smaller samples than were possible with the well-known decay-counting method, which required about 1 g of carbon. The underlying principles were articulated by Muller in 1977, who proposed using a cyclotron as the accelerator and reported the successful detection of $^{3}$H [47]. Later in the same year the first AMS observations of $^{14}$C from natural materials were reported simultaneously by two groups, one working at McMaster [48] and the other at Rochester [49]. These groups used another type of accelerator, the tandem van de Graaff, which proved to have some powerful advantages over the cyclotron (mainly due to the use of negative ion sources beneficial to the rejection of interfering molecular isobars). Subsequently, AMS has been conducted almost exclusively with tandem electrostatic accelerators [50].

The technique was rapidly embraced by the nuclear physics and $^{14}$C-dating communities. This led to the development of the first dedicated AMS systems based on the Mark I Tandetron [51], and the first three were installed at Arizona, Oxford, and Toronto in 1981–82. At the same time, several nuclear physics laboratories added an AMS component to their research programs. Techniques for other isotopes, in particular $^{36}$Cl [52], $^{129}$I [53], $^{10}$Be [54], and $^{26}$Al [55], were soon developed. Over the subsequent years, many more accelerators have been given over in whole or in part to AMS and a series of second-generation purpose-built systems are now beginning to make their mark. In 1998, there are about 45 accelerators worldwide that are actively involved in AMS [50].

In parallel with the growth in the number of facilities, applications of the technique have burgeoned. Traditional $^{14}$C dating was no longer the dominant application. Carbon-14 remains the most important isotope,

but much of the research is directed toward an understanding of global climate change via studies of oceanic circulation, atmospheric processes and past climates [56]. Cosmic ray exposure dating, which exploits the buildup of $^{10}$Be, $^{26}$Al, or $^{36}$Cl in surface rocks, was making significant contributions to studies of landscape evolution. Beryllium-10 has also been used in studies of soil processes, the deposition of ocean sediments, and the sources of volcanic rocks. Both $^{36}$Cl and $^{129}$I have been used in hydrology and in tracing the migration of nuclear waste, while $^{26}$Al and $^{41}$Ca have found application in biomedicine. New applications continued to surface, often spawning new developments in technique.

***Development of Biomedical AMS*** Biomedical applications of $^{14}$C have become increasingly important. It is the most commonly employed radioisotope in toxicology and pharmacology, although similar studies are now being conducted with $^{3}$H. Both of these isotopes can be easily incorporated into most types of organic molecules that might be of interest in biological research. Additionally, $^{26}$Al, $^{41}$Ca, $^{129}$I, and $^{10}$Be are finding new applications in biomedicine [57–59].

In 1994, AMS was first used biomedically in studies to detect small amounts of $^{14}$C-labeled carcinogens when they are bound to deoxyribonucleic acid (DNA) [60]. The benefits of using AMS for the analysis of samples derived from radiotracer studies with humans soon became apparent [46]. The maximum radioactive dose that can be administered to humans depends upon the residence time in the body and whether it is accumulated in specific tissues [61]. Under certain circumstances, for example, when there is a long pharmacokinetic half-life, the amount of radioactivity that can be administered is below the capabilities of liquid scintillation counting (LSC), the most commonly used method for the measurement of radioactivity for biomedical applications. Since the advent of biomedical AMS, it is possible to conduct radiotracer studies in humans, with the administration of such low levels of $^{14}$C that they are, from a regulatory point of view, considered nonradioactive. Biomedical AMS has been used in the study of (1) metabolism of xenobiotics in animals and humans, (2) pathways of drug metabolism, (3) biomarkers, (4) metabolism of endogenous molecules including vitamins, (5) DNA and protein binding studies, and (6) clinical diagnosis [61].

***AMS Microdosing*** Miscrodosing is the most recent innovation utilizing AMS technology. As we have discussed, choosing a drug for clinical trials from numerous promising candidates is very much a hit-and-miss business. Data are gathered from in vitro, in vivo, and in silico models in order to predict the drug's behavior in humans, but such methods are probably only about 60% predictive. Presented with a choice of good candidates, it would be better to take them all in humans. This would, however, be prohibitively expensive, as each compound would require a significant package of toxicological safety testing. Alternatively, using microdosing, each candidate drug could be given to human volunteers at very low levels of a few tens or at most a hundred micrograms. At these levels, only a limited toxicology package is required and in vivo human data can be acquired for candidate selection. Only AMS has the required sensitivity to conduct such studies at the low microgram level [61].

Currently, there are more than 50 accelerators around the world (Table 1) carrying out AMS. CBAMS Ltd. (now Xceleron, York, UK) was founded at the end of 1996 and is the first private limited company in the world to offer commercial analytical services through AMS with full quality management procedures [46]. Xceleron has been a company at the fore front of using microdoing in drug R&D. The first comprehensive study in microdosing, the Consortium for Resourcing and Evaluating AMS Microdosing (CREAM) trial, was concoducted at Xceleron. On January 31, 2006, as a proof of microdosing's potential in drug development, Xceleron was awarded €2.1 million to lead the European Union Microdose AMS Partnership Programme (EUMAPP) to promote this technology as a viable experimental technique, where 7 additional drugs will be tested via this 30-month project, which gathered together 10 organizations from 5 different countries (United Kingdom, Sweden, Netherlands, France, and Poland). So far, one drug has been registered with the microdosing study at Xceleron: Tekturna, an antihypertensive drug by Novartis registed March 5, 2007. The microdosing of Speedel SPP635, a rennin inhibitor for the treatment of hypertension, was also carried out at Xceleron. In September 2007, Xceleron struck a deal with GlaxoSmithKline (GSK) that has resulted in the drug giant commissioning the pharmaceutical industry's first in-house AMS facility. In November 2007, Xceleron opened AMS operation in Germantown, Maryland. On May 1, 2008, Corcept Therapeutics Incorporated (Menlo Park, California) announced that its lead selective GR-II antagonist, CORT 108297, produced promising results in a human microdosing study. The microdosing study was conducted at Pharmaceutical Profiles Ltd. (Nottingham, UK) under Medicines and Healthcare product Regulatory Agency (MHRA) regulatory authorization and was coordinated by Xceleron Ltd.

On January 2, 2008, U.S.-based MPI Research and China's Shanghai Medicilon formed a joint venture in preclinical services, Medicilon-MPI Preclinical Research. They will establish a facility that is expected to be fully operational by 2009 providing both GLP and non-GLP

[a]Model EN, FN, and MP are different, relatively old, tandem accelerators produced by HVEC Burlington, USA, during the 1960s and 1970s. Their original design voltages were 6, 7.5, and 10 MV, respectively. Pelletrons are produced by National Electrostatic Corporation, Madison, WI. Tandetrons were originally produced by General Ionex Corporation. They are now produced by High Voltage Engineering Europe, Amersfoort, The Netherlands.

preclinical services including IND enabling studies and assistance with IND submissions and new drug applications (NDAs) for the US and other regulated markets.

Besides Xceleron, AMS service is accessible for biochemical quantitation from several other private companies: Corsidus Inc., Vitalea Science, and Accium BioSciences. Noncommercial access to AMS is available at the National Institutes of Health (NIH) Research Resource at Lawrence Livermore National Laboratory. It is reported that 75% of the 20 leading pharmaceutical companies have now used microdosing in drug development [62].

### 4.2 Principles of AMS

***Elements Suitable for AMS Analysis*** For an isotope to be measurable by AMS, it should be long-lived with a half-life in the range of 10 years to 100 million years. Short-lived radioisotopes, with half-lives less than about 1 year, can usually be measured with high sensitivity by conventional techniques, in which decay products are

counted efficiently. Primordial radioisotopes with half-lives greater than about $10^9$ years are relatively abundant naturally (since they have not completely decayed over the life of the solar system) and are used for dating by measuring the buildup of stable decay products. Radioisotopes with half-lives in the intermediate range of $10^3$–$10^8$ years are difficult to measure with decay counting since only a small fraction of the atoms decay over a reasonable counting period of a few months or less, even though many of the interesting processes that occur on Earth and in the solar system have time scales that fall in this interval. However, they are suitable for AMS. Such isotopes have short half-lives in geological terms so that they have very low natural abundance. For example, the naturally occurring isotopic abundances of the stable isotopes $^{12}C$ and $^{13}C$ are 98.9 and 1.1%, respectively, compared to $1.2 \times 10^{-10}$% for $^{14}C$. Elements that have long-lived isotopes suitable for AMS tracing are shown in Figure 3 [63]. Elements of interest in biomedicine include C, Be, Na, Al, Ca, Cs, Hg, Si, Cl, l, Pt, Ra, U, Pu, Mn, Fe, Co, Ni, Se, Mo, Sn, Tc, and Pb [46].

The relatively long half-lives of AMS isotopes also guarantee that there is negligible decay during biological in vivo studies; decay is an important issue, particularly where administration to humans is concerned [63]. Not surprisingly, the amount of radioactivity that can be administered to humans is limited owing to the radiation exposure. Regulatory agencies across the world proscribe limits of radiation exposure based on the risk of biological damage that a given radioactive dose is likely to cause in humans [61]. The biological effect is related to the amount of energy that a given organ or tissue is likely to absorb. The biological effect dose is known as the *dose equivalent* and is defined as the absorbed dose multiplied by a factor ($Q$) depending upon the type of radiation. For low-energy β emitters, such as $^{14}C$, $Q = 1$. Units of dose equivalents are sieverts (Sv), where 1 Sv equals 1 joule of kinetic energy absorbed per kilogram bodyweight. A joule is a measure of kinetic energy over time, and therefore the radioactive dose received depends upon the amount of radioactivity and its residence time in the body. There are also weighting factors applied depending upon the tissue or organ exposed to the radioactivity. For example, a larger weighting factor is used for the gonads than for the liver. Thus, a radiolabeled compound, which is eliminated rapidly from the body, without any retention in tissues or organs, can be administered using higher levels of radioactivity than a compound that is slowly eliminated and accumulates in the testes.

Experiments have to be conducted on a compound-by-compound basis to determine the maximum amount of radioactivity that can be administered to humans. These dosimetry studies are typically performed in a pigmented rat model. A pigmented rat is used to assess the extent of binding of the compound to melanin. Such binding can, for example, lead to a localized concentration of radioactivity in the eye. For a typical drug with a plasma half-life of a few hours and that does not bind to melanin, a radioactive dose of 2–3.5 MBq per volunteer might be administered.

***Count the Atoms Directly Using AMS*** AMS overcame fundamental limitations of both decay counting and conventional mass spectrometry [50]. Using $^{14}C$ as an example, there are $6 \times 10^{10}$ atoms of $^{14}C$ in a 1-g sample of modern carbon (the carbon after the era of the above-ground nuclear tests in several countries between 1955 and 1963, which dramatically increased the amount of carbon-14 in the atmosphere and subsequently in the biosphere), which decays 14 times per minute. In order to achieve 0.5% statistical precision with decay counting, it would be necessary to count for 48 h. In contrast,

typical $^{14}C$ counting rates in an AMS system are ~100 $s^{-1}$, where the same precision can be reached in 10 min, and a sample size of 1 mg is all that is required.

The half-life of $^{14}C$ is 5730 years, so it takes that long for half the $^{14}C$ atoms in a sample to decay. In any one year, therefore, only 0.012% of the $^{14}C$ atoms decay. For the rate of one disintegration in a second $4.3 \times 10^9$ atoms of $^{14}C$ must be present. It is therefore a far more sensitive method to directly detect $^{14}C$ atoms themselves, rather than detecting the radiation emitted from decaying $^{14}C$ atoms [8] since the detector is waiting the decay almost all that time.

AMS offers $10^3$–$10^9$ fold increases in sensitivity over the decay counting methods [63]. Decay counting indirectly determines the number of isotope nuclei present by measuring decay events, which is dependent on the measurement time and amount of sample analyzed. AMS, which directly quantifies each individual isotopic nucleus, is independent of these variables, therefore, can dramatically reduce analysis time and amount of sample required.

A conventional mass spectrometer (MS) can in principle count a much higher fraction of the $^{14}C$ atoms in a sample than decay counting, but in practice the $^{14}C$ ions are masked by relatively intense fluxes of ions of the $^{14}N$ isobar, by background from the stable isotopes $^{12}C$ and $^{13}C$, and also by molecular ions such as $^{13}CH$, $^{12}CH_2$, $^{12}CD$, and $^{7}Li_2$. Mass difference between isobars (atoms or molecules having the same mass number $M$) can be very small. The required mass resolution is $\Delta M/M = 84{,}000$ for $^{14}C$–$^{14}N$. In such cases isotopes can be resolved with sector MS only when very narrow slits are used, and this results in low efficiency for the transmission of ions through the instrument. *AMS obtains much better sensitivity by opening the slits wide for maximum transmission and finding other ways to separate atomic and molecular isobars.* It is possible in principle to build a mass spectrometer that could resolve these isobaric and molecular interferences, however, detected $^{12}C$ currents in such a device would be limited to 1 nA or less, and the corresponding flux of $^{14}C$ ions would be less than $10^{-2}\,s^{-1}$, that is, the rate would be comparable to decay counting. In contrast, detected $^{12}C$ currents in a typical AMS system are ~20 $\mu$A [50]. The lowest isotope ratios measurable by conventional mass spectrometers are ca. $10^{-10}$ (rare/abundant). This is about five orders of magnitude above measurements using AMS [46].

MS is an analytical method that makes use of the fact that each atomic and many molecular species have unique masses. MS typically involves four separate steps: (i) the formation of a charged atomic or molecular ion; (ii) acceleration through an electrostatic (ES) potential of a few kilovolts; (iii) separation of the ions based on their mass-to-charge ratio using some combination of the four basic analysis stages: (a) magnetic field, to distinguish mass × energy/charge$^2$, (b) electrostatic field to distinguish energy/charge, (c) velocity selector (also called a Wien or E × B filter, consists of perpendicular magnetic and electrostatic fields that provide zero net force on particles of the selected velocity, time-of-flight detectors also select ions based on their mass-to-energy ratio) to distinguish mass/energy, and (d) cyclotron resonance to distinguish mass/charge. Any two of these methods placed in series will select partciels that have unique mass-to-charge and energy-to-charge ratios; and (iv) measurement of the number of ions per second in a detector (or the electric current in a Faraday cup). AMS uses these four steps but includes an acceleration to megaelectron volt energies. *High energies* together with the analysis of *negative ions* allow the separation and measurement of isotopes at abundance ratios far lower than possible at low (kiloelectron volt) energies [64]. The high energy available is most suitable for isobar separation by ionization counter measurements [65].

The sensitivity limitations of conventional mass spectrometry are mainly the result of [46]:

1. Molecular interferences that cannot be distinguished from the wanted atom, except on the basis of differences in mass due to mass defects
2. Small-angle elastic scattering of ions of the intense mass into adjacent weak mass peak
3. Metastable decomposition and large-angle scattering from the walls or by residual gas molecules causing unwanted particles to arrive at the final detector
4. Isobaric ions of the same A, but different Z, which cannot be distinguished from the wanted ions (in combinations of electric and magnetic fields), except by the use of extremely high mass resolution
5. Particles whose kinematic properties (E/Z; $m/z$) mimic the deflection kinematics of the wanted particle at each point through the instrument unless high mass resolution is employed
6. Low probability charge-changing sequences that modify the kinematic properties of the unwanted ions at appropriate points through the instrument so they arrive in the detector volume

The very high sensitivity of AMS is obtained by an appropriate combination of energy, mass, and charge spectrometry, as the ions have at all times characteristic ratios of energy divided by charge ($E/q$) and mass divided by charge ($M/q$) that may change in a controlled manner during their passage through the spectrometer [65].

### 4.3 Procedure of Human Microdosing Study Using AMS

For a microdosing study, patients or volunteers are administered a drug that is isotopically enriched with $^{14}C$. At time intervals after drug administration, blood, urine, feces, and, very rarely biopsy samples are collected for analysis. Extreme care must be taken in preparing samples for AMS analysis to prevent any contamination and, therefore, to ensure that the isotope detected in the sample is actually associated with the labeled compound under investigation, or that the sources and amounts of any carbon introduced during processing are known. Consequently, many precautions are taken, and include sample handling in a designated laboratory and the use of disposable labwear to minimize the potential for contamination [66]. It is also important to ensure that the amount of isotope present in a sample does not exceed the dynamic range of the spectrometer because that excess could contaminate the instrument [63].

Before these biological samples can be analyzed by AMS, the carbon in the sample has to be converted to graphite. The advantages of analyzing solid samples derived from biological material include a decreased risk of cross contamination in the ion source and shorter memory effects when a sample that contains high $^{14}C$ concentrations is encountered. Furthermore, graphite can be prepared at any location and sent to an AMS facility for analysis; that process affords multiple researchers who conduct a wide variety of experiments access to an instrument at the same time.

Graphite for analysis of $^{14}C$ is obtained in a two-step process via oxidation of the crude sample [e.g., DNA, protein, or high-performance liquid chromatography (HPLC) fraction] by cupric oxide to a gaseous mixture of carbon dioxide, water, and nitrogen. The carbon dioxide is cryogenically extracted and reduced to yield filamentous graphite [67]. An improved procedure [68] involves transfer of combustion products from a sealed tube that contains the oxidized biological sample to a septa-sealed vial that contains zinc dust and catalytic iron powder. The vial is kept in liquid nitrogen to cryogenically trap the carbon dioxide and water (which act as a source of hydrogen gas), whereas noncondensing gases are removed by vacuum pump. After heating at 500°C, the resulting graphite/iron mixture is packed into a sample holder and is ready for AMS analysis. Generally, three to seven replicate measurements of a single graphite sample are taken to obtain at least a 3% precision. The measured isotope ratios are normalized against graphitized ANU (Australian National University) sucrose standards that are analyzed at the same time and have an accepted $^{14}C/^{12}C$ ratio of 1.5081 Modern [63].

AMS enables the measurements of drug concentrations in plasma and body fluids. Samples of blood and excreta can also be analyzed by chromatographic methods such as HPLC in order to separate the metabolites of the drug. The HPLC eluate is collected as a series of fractions that are then analyzed by AMS. Although AMS does not provide any direct information on chemical identity, the extent of metabolism can be assessed from the radio-chromatographic profile and, if authenticated standards are available, some metabolite comparison can be undertaken on the basis of chromatographic retention time [8].

Ideally, approximately 0.5–1 mg of total carbon is required for AMS analysis. Samples that yield this amount of carbon upon graphitization (e.g., tissue, protein) can be measured directly, whereas smaller samples (e.g., HPLC fractions, DNA) can be supplemented with a known amount of a carrier to provide sufficient carbon for optimal sample preparation. Carriers should contain depleted levels of $^{14}C$, such as the commonly used tributyrin, a petroleum-based nonvolatile liquid, 1 mL of which provides 0.6 mg carbon. In determining the accurate amount of $^{14}C$ in a sample by AMS, it is vital that the complete carbon inventory is known. This information can be obtained by conducting elemental analysis or alternatively, published reference values for a particular tissue type can be used. Results from AMS analysis are expressed in terms of "fraction modern" or "percent of modern carbon" (pMC), and can be converted to more relevant forms by subtracting the amount of $^{14}C$ contributed by the natural radioisotopic abundance of the sample plus any added carrier and taking into account the specific activity of the labeled compound [63].

### 4.4 Instrumentation of AMS

The principle of AMS analysis is to isolate the radioisotope of interest from all other interfering molecular and nuclear isobars to enable the direct quantitation of the radioisotope relative to a chosen stable isotope (isotope ratio). It achieves this by [50]:

1. Using negative ions ($C^-$, in the case of $^{14}C$, are generated in the ion source by cesium sputtering from a graphite target; target from various samples can be flexibly changed, which permits high throughput). The negative ions are separated based on mass by passing through a low-field magnet. Ions such as $^{13}CH^-$ and $^{12}CH_2$ are also present at this stage.
2. Dissociating molecular ions and stripping atomic ions to high positive charge states after a first-stage acceleration. The tandem electrostatic accel-

erator generates a high voltage (commonly 1–10 MV) to accelerate $C^-$ ions. At the positive terminal, they are stripped of several electrons, as a result of either passing through a thin molecular dissociator foil or a localized gas. Importantly, it is this process that eliminates molecular isobars because these are destroyed in the charge-changing collisions. The number of electrons removed increases with ion velocity; $^{14}C$ is most typically measured in the 3+ or 4+ charge state [63].

3. Using a second stage of acceleration followed by identification of individual ions. The positively charged ions are repelled by the positive high terminal voltage and are accelerated toward the exit and leave the accelerator (the term tandem accelerator is derived from this two-stage "pull–push" effect). They are further separated based on energy and charge through an electrostatic analyzer prior to entering a mass spectrometer that selects for the appropriate ions (e.g., $^{14}C^{4+}$, or $^{13}C^{4+}$). Individual ions are counted in a detector (e.g., gas-ionization chamber), which identifies isotopes by their characteristic pattern of energy loss, and therefore discriminates against any nuclear isobars. AMS measurements are an isotope ratio, for example, $^{14}C/^{13}C$ or $^{14}C/^{12}C$; therefore, a stable isotope of the same element ($^{13}C$ or $^{12}C$) is selected sequentially and is measured as an electrical current in an off-axis Faraday cup after acceleration and mass analysis since it is $10^{12}$ times more abundant than the rare isotope [63].

The van de Graaff tandem accelerators have some powerful advantages over the cyclotron. Tandem accelerators use negative ions in the first acceleration stage. Mass spectrometry of negative ions is a powerful method for rejecting isobars (such as $^{14}N^-$, $^{26}Mg^-$, $^{55}Mn^-$, $^{129}Xe^-$). The negative ion is not stable for some atoms and molecules (including N, Mg, $KH_3$, and noble gases), and this has made possible AMS of $^{14}C$, $^{26}A1$, $^{41}Ca$, $^{55}Fe$, and $^{129}I$ [10, 64]. Tandem accelerators have the following characteristics: (i) the ion source and detector are located at ground potential; (ii) they do not require pulsed beams; (iii) the electron-stripping step needed to eliminate molecules is an integral step in the operation of the accelerator; and (iv) transmission through the accelerator and subsequent analyzers can be made independent of small changes in the terminal voltage.

Figure 4 illustrates the essential features of an AMS system. AMS can in principle be described by the following steps [10]: negative ion production, selection of ion mass by a magnet, acceleration of the negative ions, charge exchange of the ions from negative to positive, acceleration of the now positive ions, selection of [mass × velocity/(charge)$^2$] and/or [velocity] and/or [charge/energy] in one or several analyzing units, and finally particle detection. The many steps from ion source to detector cause a strong reduction of the background. Three characteristics of AMS with tandem accelerators provide the possibility to measure low isotope ratios, for example, for $^{14}C/^{12}C$ down to $10^{-15}$.

**Figure 4** Essential features of an AMS system. The first magnet is shown as transmitting mass-14 negative ions. It is also set periodically to transmit mass-12 and mass-13 ions, in which cases the accelerated ions are detected in the off-axis cups after the analyzing magnet [63].

Because biomedical studies are concerned with measuring much higher concentrations of $^{14}C$, it is possible to achieve the required degree of precision and sensitivity by measuring $^{14}C$ in the 1+ or 2+ charge states. This

**Figure 5** Schematic layout of the National Electrostatic Corporation Model 3SDH-1 1 MV Pelletron tandem AMS instrument at the Center for Accelerator Mass Spectrometry and part of the NIH National Resource for Biomedical AMS located at Lawrence Livermore National Laboratory. This system has been in routine operation for the analysis of $^{14}C$ in biological samples since April 2001 [63].

lower charge state permits the use of a 1-MV accelerator [69–71]. Consequently, much smaller, cheaper, and lower maintenance instruments became available for the analysis of biological specimens.

Figure 5 shows the layout of the AMS system operated at Lawrence Livermore National Laboratory [11]. The carbon from the reduced sample is pounded into cylindrical target cathodes, which are mounted in a 64-sample wheel and placed inside a cesium sputter ion source. Atomic Cs vapor is produced from a heated cesium reservoir and sprayed onto a heated ionizer surface, producing $Cs^+$ ions that are accelerated toward the target held at −8 kV. The $Cs^+$ ions sputter carbon atoms and ions from the target that are ionized to $C^-$ ions as they pass through a condensed cesium layer on the cathode. Negative ions at $m/z$ 13 ($^{13}C^-$) and 14 ($^{14}C^-$) are pulsed through an injection magnet into a tandem electrostatic van der Graaff accelerator. Negative $C^-$ ions are accelerated toward the high-voltage terminal (+518 kV) in the center of the accelerator where they are converted to positive ions, $C^+$ being the most abundant, in an argon gas electron stripper. The positive ions are repelled toward the high-energy exit of the accelerator held at 0 V. $^{13}C^+$ and $^{14}C^+$ ions are then separated by momentum using a high-energy analyzing magnet (the analyzing magnet in Fig. 5). The beam currents of the abundant stable isotopes $^{12}C$ and $^{13}C$ are measured in Faraday cups. The $^{12}C$ cup is positioned after the injection magnet and before the accelerator, whereas $^{13}C$ cup is positioned between the analyzing magnet and the 90° electrostatic spherical analyzer (ESA). The $^{14}C^+$ ions are energy analyzed and focused in the ESA, detected, and counted by a silicon surface barrier particle detector using total energy deposition per ion to set the measurement gate. Molecular isobars at $m/z$ 14, such as $^{13}CH^-$ and $^{12}CH_2^-$, are the most abundant mass 14 ions and also pass through the injection magnet but dissociate in the electron stripper within the accelerator. $^{14}N^-$ ions decay on a femtosecond time scale and do not interfere with the analysis.

The normalized $^{14}C$ concentrations are easily converted into moles of $^{14}C$ per gram of carbon, becquerels

(Bq) per gram of carbon, or any other convenient unit. Since AMS was first applied to $^{14}C$ dating, the Modern unit is often used. One Modern is defined as the radiocarbon activity of a sample of 1950 wood growing in the Northern Hemisphere, 13.56 dpm per gram of carbon, which is equivalent to 6.11 fCi $mg^{-1}$ or 97.8 amol $^{14}C$ $mg^{-1}$ carbon. This is the atmospheric $^{14}C$ concentration due to cosmic radiation. Since the midnineteenth century, two anthropogenic sources have significantly changed the atmospheric $^{14}C$ levels: the burning of fossil fuels (decreasing the $^{14}C$ concentration) followed by atmospheric nuclear weapons tests, doubling the concentration of $^{14}C$ in the atmosphere by 1963. This excess $^{14}C$ continues to dissipate into the oceans with a half-life of 15 years, and the current atmosphere has a $^{14}C$ concentration of 1.04 Modern. This rapid increase and subsequent dissipation of atmospheric $^{14}C$, known as the "bomb pulse" (Fig. 6), can be used to measure age or molecular turnover rates on the time scale of years or decades in organisms that have lived after the1960s. This is of particular interest in neuroscience since turnover rates in the human brain and deposition rates of pathological structures extend to these time scales, or the lifetime of the organism. The use of $^{14}C$ to determine the age of biological samples assumes that an organism's biosynthesis is in isotopic equilibrium with its carbon source(s). Since the $^{14}C$ concentration intercepts the bomb curve at least twice, dates derived by this method are ambiguous and resolving this ambiguity requires additional information.

Figure 7 shows the 5-million-volt van der Graaff tandem accelerator mass spectrometer based at Xceleron Ltd., York, UK. Figure 8 is its floor layout.

## 5 POSITRON EMISSION TOMOGRAPHY

### 5.1 Short History of PET

***Discovery of the Positron and Its Medical Applications*** P.M. Dirac postulated the existence of positive electrons (positrons) in1932 based on the equations of quantum mechanics and Einstein's theory of relativity [72]. Anderson observed positrons in the cosmic ray in 1932 [73]. The first cyclotron was

**Figure 6** Atmospheric nuclear weapons tests in the 1950s and 1960s added significant amounts of $^{14}C$ to the environment. This bomb curve can be used for dating recent biological material. Superimposed on the bomb spike is the addition of $^{14}C$-depleted $CO_2$ from burning fossil fuels [11].

**Figure 7** The 5-million-volt van der Graaff tandem accelerator mass spectrometer based at Xceleron Ltd, York, UK. (Photo source: Nature review 2003).

**Figure 8** AMS system at Xceleron (former CBAMS) Ltd, the first private limited company in the world to offer commercial analytical services through AMS [46].

developed by Ernest Lawrence and his team around this time in Berkeley, California: two D-shaped magnets capable of accelerating particles to produce progressively higher energy protons and deuterons that could then bombard elements to explore the nature of the atomic nucleus [74]. By 1938 Lawrence, Livingston, and others had designed a "medical cyclotron" [75]. The fusion of the theory and experimental observation led to the development of larger cyclotrons able to produce large quantities of artificial radioisotopes such as carbon-11, nitrogen-13, oxygen-15, and fuorine-18, isotopes that found many uses in medical and physiologic research. The introduction of F-18 deoxyglucose represents another major step toward practical clinical use of positron-emitting tracers. We have now achieved the transition from the postulation of the existence of positrons to their use in a wide variety of diseases [75].

***Evolution of Positron Emission Tomography*** In1951, the first medical applications for the positron were made and reported by Sweet at Massachusetts General Hospital (MGH), which utilized coincidence to localize brain tumor [76, 77]. In the same year, Wrenn et al. published studies using annihilation for localizing brain tumors [78]. In 1954, David Kuhl developed a photorecording system for radionuclide scanning [79] that has become the standard for all nuclear medicine diagnostic procedures throughout the world. In 1962, he developed radionuclide emission tomography with Roy Edwards [80], leading to the first "computer tomography," which ultimately led to the development of the X-ray computed tomography (CT) scanning as well as positron emission tomography (PET) scanning. Their work later led to the design and construction of several tomographic instruments at the University of Pennsylvania. Tomographic imaging techniques were further developed by Michel Ter-Pogossian, Michael E. Phelps, and others at the Washington University School of Medicine, where the first PET tomograph (PETT I, 1973) and first human PET tomograph (PETT III, 1974) was built. The first commercial PET scanner was designed at EG&G ORTEC in collaboration with Phelps and Hoffman as a commercial version of PETT III. The historical development of PET is marked by numerous significant technological accomplishments driven by an unprecedented

collaboration between multidisciplinary groups of investigators with backgrounds in medical sciences, physics, chemistry, mathematics, bioengineering, and computer science [77].

The scintillation detector material used in PET is the determining factor in the sensitivity. The scintillation process involves the conversion of photons (511-keV γ rays) into visible light via interaction with a scintillating material. Increased light yield, faster rise and decay times, greater stopping power and improved energy resolution, linearity of response with energy, in addition to low cost, availability, mechanical strength, moisture resistance, and machinability are the desired characteristics of scintillation crystals (Table 2) [81]. The replacement of NaI(Tl) crystals with bismuth–germanate-oxide (BGO) crystals, which is very dense, non-hygroscopic, and has a high effective atomic number, greatly improved the detection efficiency for the high-energy 511-keV γ ray. The first evaluation of BGO for use in PET was performed in the late 1970s by Cho and Farukhi [82], and Derenzo [83]. Lutetium oxyorthosilicate ($Lu_2SiO_5$, LSO) crystal has a slightly greater density, slightly lower effective atomic number, and has 5 times more light output than BGO. Also the light output of LSO has 7.5 times faster decay (a key requirement for high counting rates) than BGO. This LSO performance results in a combination speed and light output improvement of 37.5 over BGO [77]. Tomographs using LSO promise to dominate PET in the 2000 with patient throughput improvement of a factor of 5 or greater and with no increase in cost over BGO tomographs [77].

In 1978, Tatsuo Ido et al. at the Brookhaven National Laboratory first described the synthesis of $^{18}$F-tagged deoxyglucose ($^{18}$F-FDG), the most commonly used PET scanning isotope carrier [84]. The compound was first administered to two normal human volunteers by Abass Alavi in August 1976 at the University of Pennsylvania. Brain images obtained with an ordinary (non-PET) nuclear scanner demonstrated the concentration of FDG in that organ. Hamacher et al. [85] at Julich in Germany later developed a new synthesis method for FDG using a nucleophilic reaction (F-18 ion), which has become the synthesis of choice for FDG today.

In 1990s, the entrance of two major image companies (General Electric and Siemens) validate PET for clinic applications [77]. PET as the molecular imaging technology of molecular medicine may well exceed the incredible success and contributions made by CT (X-ray computed tomography) and MRI (magnetic resonance imaging) [77, 86, 87]. Figure 9 demonstrates the ability of PET observation of various biological processes [88]. The advantages of PET is that PET imaging (1) can show the extent of the disease; (2) can help in monitoring treatment and shows its effectiveness; (3) reveals disease earlier, can diagnose faster; (4) can detect whether a mass is benign of malignant; and (5) can detect abnormalities before there is an anatomical change. In contrast, CT and MRI detect changes in body structure, and simply confirm the presence of a mass. Figure 10 demonstrates that PET imaging is sensitive to the biological process of disease [88]. One survey in 2003 indicated the average cost per scan of PET in six U.S. veterans affairs hospitals and two academic medical centers was $1885 using manufactured FDG and $1898 using purchased FDG.

Since the beginnings of PET, the technique has been applied to many areas of medicine. It is especially useful in imaging neurological and psychiatric disorders, heart

**Figure 9** PET studies of glucose metabolism to map the human brain's response in performing different tasks. Subjects looking at a visual scene activated visual cortex (arrow), listening to a mystery story with language and music activated left and right auditory cortices (arrows), counting backwards from 100 by 7's activated frontal cortex (arrows), recalling previously learned objects activated hippocampus bilaterally (arrows), and touching thumb to fingers of right hand activated left motor cortex and supplementary motor system (arrows). Images are cross sections with the front of brain at top. Highest metabolic rates are dark, with lower values in grays [88].

**Figure 10** PET images of glucose metabolism in various types of cancers. Study illustrates that increased glycolysis is a common property of cancer, independent of organ of origin. In breast example, a 6-mm lesion is just behind a 10-mm one. Mammogram was normal, and tumor had high expression of HER-2/neu oncogene. Arrows point to some tumors [88].

disease, and cancer [89]. Despite the obstacles in its development and practice, the reason people were drawn to PET in the first place remains: its ability to provide high-quality images of a biologic process in vivo with minimal dose to the patient. Hence PET will be the natural choice for human microdosing [12, 90–92].

### 5.2 Principles of PET

***Procedure*** The general procedure to perform a PET is (1) production of positron-emitting isotope in a cyclotron; (2) chemistry of labeling compound with positron emitter and preparing compound in a form suitable for

administration in humans; (3) transport of labeled compound from chemistry group to camera group; (4) administration (injection intravenously) of tracer compound and data acquisition with PET camera; (5) processing of data from PET camera to extract information related to the tracer's kinetics in the body: tissue concentration of the probe and labeled product over time. These data are combined with a measure of the time course of the plasma probe concentration, representing its delivery to tissue, and processed with a compartmental model containing equations describing the transport and reaction processes the probe undergoes [88]; and, finally, (6) interpretation of result. Common tissue concentrations of PET probes are in the range of pico- to femtomoles per gram. Over 500 molecular imaging probes have been developed and consist of various labeled enzyme and transporter substrates, ligands for receptor systems, hormones, antibodies, peptides, drugs (medical and illicit), and oligonucleotides [88].

***Positron–Electron Annihilation and γ-Ray Coincidence Detection*** Figure 11 diagrammatically represents the principles behind PET. It relies on the unique physics of radionuclides that decay via positron ($\beta^+$) emission. Within 1–2 mm, the positron collides with an electron present in the atoms making up surrounding tissues. On collision, the positron and electron annihilate each other, emitting two γ rays each of 511 keV energy, at 180° apart. These high-energy γ rays have an average path length of about 10 cm in tissue before they are scattered or absorbed and thus have a high probability of escaping the body. If both γ rays can be externally detected and localized in space, this forms a valid "coincidence" event and determines a line passing through the object that intersects the position at which the electron–positron annihilation took place. This, in turn, closely approximates (typically within tenths of a millimeter for low-energy positron emitters) the location at which the positron was emitted. A PET scan consists of the collection of large numbers of these coincidence events. Using mathematical reconstruction methods and appropriate correction factors for phenomena such as γ-ray attenuation and scatter, it is then possible to compute cross-sectional images through the object that quantitatively reflect the concentration of the positron-emitting radionuclide inside an object. By synthesizing compounds tagged with positron-emitting radionuclides and injecting these into the body, the regional concentration of the labeled compound (in $\mu Ci/cm^3$) can be imaged in vivo as a function of time [93]. The technique is therefore noninvasive and quantitatively measures the dynamic three-dimensional (3D) distribution of the drug in the body.

**Figure 11** Principle of positron tomography (PET) [8]. A labeled ligand emits a positron ($\beta^+$).Within a few tenths of a millimetre, the positron collides with an electron present in the atoms making up surrounding tissues. On collision, the positron and electron annihilate each other, emitting two γ rays at 180° apart. The γ rays are detected by a detector array. Opposite detectors must register the γ rays (coincidence detection) for the signal to be accepted as real.

***Positron-Emitting Radionuclides and Radiopharmaceuticals*** There are a large number of available positron-emitting radionuclides, most of which are produced by accelerators [94]. Some of the more frequently used positron-emitting radionuclides for biological applications are shown in Table 3.

Table 3 emphasizes one of the key strengths of PET, in that elements that are commonly found in molecules of biological interest, such as oxygen, nitrogen, and carbon, have positron-emitting isotopes. There is no positron emitter of hydrogen, so fluorine-18 is used as

**TABLE 3 List of Positron-Emitting Radionuclides Used in PET Applications**

| Radionuclide | Half-Life | Maximum Energy of Emitted Positrons |
|---|---|---|
| **C-11** | **20.3 min** | **0.96 MeV** |
| **N-13** | **9.97 min** | **1.19 MeV** |
| **O-15** | **122 sec** | **1.72 MeV** |
| **F-18** | **109.8 min** | **0.64 MeV** |

| Br-76 | 16.1 h | 3.68 MeV |
| Rb-82 | 1.27 min | 3.3 MeV |
| I-124 | 4.17 days | 2.1 MeV |

*Source*: From ref. 93.

a hydrogen substitute. Positron emitters of Cu, Zn, K, Br, Rb, I, P, Fe, Ga, and others are also used [88]. Thus, in theory, any biological molecule can be labeled with a positron emitter by direct substitution, resulting in a labeled compound with virtually identical biochemical properties to the native compound. However, the half-lives of these radionuclides are very short, necessitating on-site production with a small biomedical cyclotron and also posing challenges in relation to extremely rapid synthesis of labeled compounds.

The four radionuclides in bold in Table 3 are produced in compact biomedical cyclotrons and are the most commonly used PET radionuclides. The positron energy determines the distance a positron will travel in tissue prior to annihilation and can limit spatial resolution of PET images in very high-resolution systems.

Fluorine-18 is a commonly used positron-emitting radionuclide, as its half-life of 110 min allows it to be produced and distributed by regional facilities (so that on-site cyclotrons are no longer a requirement), and this also gives sufficient time for more complex synthetic pathways to produce labeled compounds. Fluorine-18 can be used to substitute for H atoms, creating labeled analogs, whose properties are often similar to that of the native unlabeled compound, depending on the perturbation at the labeling site and its biological consequences. As PET becomes more widespread, other radionuclides are being investigated, particularly metals such as gallium-68 and copper-62, which can be produced in generator form and therefore do not require a nearby cyclotron [95].

Many hundreds of different compounds have been synthesized with positron-emitting labels, with carbon-11 and fluorine-18 by far the most widely used radionuclides [96]. A sample listing of the different biological processes that can be measured in vivo by PET using direct substitution and analog tracers is shown in Table 4. With appropriate labeling and understanding of the in vivo behavior of the labeled compound, just about any biological process of interest is amenable to in vivo investigation by PET [93].

*Fluorodeoxyglucose* $^{18}$FDG is used in neurology, cardiology, and oncology to study glucose metabolism. FDG is potentially useful in differentiating benign from malignant forms of stimulated osteoblastic activity because of the high metabolic activity of many types of aggressive tumors.

*Oxygen* $^{15}$O-labeled water and oxygen are being evaluated for the quantification of myocardial oxygen consumption and oxygen extraction fraction. $^{15}$O-labeled oxygen can also be used to measure tumor necrosis.

**TABLE 4 Small sample of PET Radiopharmaceuticals and the Biological Process That They Are Used to Measure**

| Desired Measurement | Examples of PET Radiopharmaceuticals |
|---|---|
| Blood volume | $^{11}$CO, C$^{15}$O |
| Blood flow | $^{15}$O-water, $^{15}$O-butanol, $^{13}$NH$_3$, $^{54}$Cu-PTSM |
| Hypoxia | $^{18}$F-misonidazole, $^{64}$Cu-ATSM |
| Substrate metabolism | $^{18}$F-fluorodeoxyglucose, $^{15}$O$_2$, $^{11}$C-acetate, $^{11}$C-palmitic acid |
| Protein synthesis | $^{11}$C-leucine, $^{11}$C-methionine, $^{11}$C-tyrosine |
| DNA synthesis (proliferation) | $^{18}$F-deoxyfluorothymidine, $^{11}$C-thymidine |
| Enzyme activity | $^{11}$C-deprenyl, $^{18}$F-deoxyuracil |
| Receptor ligands | $^{11}$C-raclopride, $^{18}$F-fluoroethylspiperone, $^{11}$C-carfentanil, $^{11}$C-WAY100635, etc. |
| Drug distribution/ kinetics | $^{11}$C-cocaine, $^{13}$N-cisplatin, $^{18}$F-fluorouracil, $^{18}$F-fluconazole |
| Receptor gene expression | $^{18}$F-fluoropenciclovir, $^{124}$I-FIAU |

*Source*: From ref. 93.

*Ammonia* $^{13}$N-labeled ammonia can be used to measure blood flow.

*Leucine* $^{11}$C-labeled methionine and leucine can be used to evaluate amino acid uptake and protein synthesis, providing an indicator of tumor viability.

*Fluorine Ion* Radiolabeled fluorine ion $^{18}$F$^-$ was once a standard agent for clinical bone scanning.

***Sensitivity of PET Assays*** A major strength of PET is that detection of radioactivity can be an extremely sensitive assay. Combined with high specific activities of the labeled compounds (typically in the range of 103–104 Ci/mmol for fluorine-18 and carbon-11), the total mass of compound that needs to be injected to create images is typically of the order of $10^{-6}$–$10^{-8}$ grams. Within the spectrum of macroscopic medical imaging, sensitivity ranges from the detection of millimolar to submillimolar concentrations of contrast media with CT and MRI, respectively, to picomolar concentrations with PET, a $10^8$–$10^9$ difference. The sensitivity of in vivo tracer studies is achieved par excellence with PET, which uses electronic collimation and thereby operates with a wide acceptance angle (particularly when operating in a fully three-dimensional mode) for detecting emitted annihilation photons. Consequently, the sensitivity of PET per disintegration, with comparable axial fields of view, is two orders of magnitude greater than

that of single-photon emission computed tomography (SPECT). Thus, PET studies in humans are, almost without exception, tracer kinetic experiments in which the underlying biological systems are not being perturbed by mass effects. This may not always be true in small-animal experiments in which mass effects need to be carefully considered under some circumstances because of the ~2500-fold difference in body weight between the human and the mouse [93].

### 5.3 Instrumentation of PET

Figure 12 illustrates historical developments highlighting the improvement in image quality and spatial resolution of clinical brain PET images resulting from the improvement of both the intrinsic performance of PET scanners and image correction and reconstruction algorithms. Both the academic community and the nuclear medicine industry maintain a continuous learning cycle and assessment of product quality to advance the technology and the operational capabilities of PET tomographs [97].

The presentation and comparison of the state-of-the-art dedicated PET systems actually available on the market in terms of physical performance and technical features can be found in refs. 98 and 99.

#### *Hardware*

*Typical PET Configuration* Modern PET scanners for clinical or human research typically consist of rings of position-sensitive scintillation detectors, with up to 25,000 individual scintillator elements of the order of 3–6 mm on a side, by 3 cm long, arranged into modular detectors (Figs. 13 and 14) [100, 101]. Detector resolution is largely determined by the width of the crystal elements. This leads to a final image resolution of ~4 mm in the best systems and an absolute detection efficiency of ~2%–3%, limited largely by solid-angle coverage constraints, which in turn are limited by cost considerations. Because of this relatively low detection efficiency and limits on radiation dose that may be given to normal human subjects, the image resolution achievable in human PET images is almost always limited by the number of detected events and the statistical noise associated with the counting statistics. To achieve satisfactory signal to noise, images are typically reconstructed at 4–8 mm resolution for brain images and perhaps 8–16 mm for whole-body images.

For very high resolution applications (detector sizes <4 mm), the physics of the positron emission and annihilation process can start to become noticeable [102]. Image resolution is then also affected by the positron range (the distance the positron travels before annihilation) and the noncollinearity of the two 511-keV $\gamma$ rays, which in practice are emitted with a small distribution of angles around 180°. The resolution in the final PET image is a convolution of these three factors (detector dimensions, positron range, noncollinearity), and for very small detector sizes, blurring due to positron range and noncollinearity can become significant and ultimately limiting. Positron range depends on the energy of the emitted positrons (see Table 3, higher energy positrons have longer ranges in tissue prior to annihilation) and varies from an average range of approximately

**Figure 12** Illustration of the significant improvement in clinical $^{18}$F-FDG brain PET image quality and spatial resolution resulting from the improvement in scanner performance for each generation during the last three decades [97].

**Figure 13** Schematics of a PET acquisition process [107, 108].

**Figure 14** Schematic view of a detector block and ring of a PET scanner [108].

0.25 mm for fluorine-18 up to 2–3 mm for high-energy emitters such as rubidium-82. The additional blurring due to noncollinearity depends linearly on the diameter of the detector ring in the PET scanner. These two factors place a limit of about 2.5 mm on the image resolution attainable in a whole-body human PET scanner with fluorine-18 labeled compounds. In small-animal PET scanners, because of the smaller ring diameter of the scanner (reducing blurring due to noncollinearity), it may be possible to reach submillimeter image resolution in vivo [93].

Phoswich (photodetector sandwich) detectors received considerable attention for the design of high-resolution scanners dedicated for brain, female breast, and small-animal imaging. It may be implemented with solid-state photodiode readouts, which also allows electronically collimated coincidence counting. Such a design has been implemented on the ECAT high-resolution research tomograph (HRRT) with LSO crystals and photomultiplier tube (PMT)-based readout [103]. Figure 15 illustrates the principle of the conventional detector block [104] and the phoswich approach [105], where two detectors are assembled in a sandwich-like design; the difference in decay time of the light is used to estimate depth in the crystal where the interaction occurred. The recently proposed axial arrangement of a matrix of long scintillator crystals readout on both extremities by hybrid photon detectors with matched segmentation is also shown [106].

In the conventional detector block concept, each block (e.g., $8 \times 8$ crystals) is readout by an arrangement of four standard PMTs optically coupled to the block by means of a light guide, which spreads the light from the individual crystals over all four PMTs. The centroid corresponds to the true interaction point of the annihilation photon, in case of conversion by photoelectric effect, or to the energy-averaged mean position of the interaction in case of occurrence of Compton scattering in the detector. The phoswich technique is able to roughly halve the uncertainty of the depth of interaction (DOI), and, hence, significantly reduces the parallax error, which is inherent to all radial geometries (such as the ring in Fig. 13). However, the phoswich approach is still only a compromise between the maximum crystal

**Figure 15** Sketch of the range of different geometric arrangements of PET detector modules. (A) Conventional radial arrangement of block detectors consisting of a set of crystals having cuts of different depths acting as light guides and segmenting the block into 64 (8 × 8) detection elements in this example. The block is optically coupled to four photomultiplier tubes at the back, and the crystal in which photon absorption occurs is identified by comparing the outputs of the four photomultiplier tubes (Anger logic). (B) Detector block consisting of a phoswich (detector 1 and 2) with depth-of-interaction measurement capability. (C) Axial arrangement of a matrix of long scintillator crystals readout by hybrid photon detectors (HPDs) with matched segmentation. In this prototype configuration, two round HPD photodetectors are coupled to the matrix of scintillators [97].

length, which can be tolerated for parallax error reasons, and the minimum length, which is required to achieve high detection efficiency. In addition, the phoswhich approach demands a delicate pulse shape discrimination of the analog signal delivered by the PMTs in order to identify the hit crystal layer. The readout electronics becomes inevitably more complex and possibly limits the data acquisition rate. The axial arrangement of long finely segmented arrays of long high-Z scintillation crystals coupled to highly pixelated photodetectors leads to an essentially parallax-free geometry, which allows reconstructing the interaction point of the annihilation photon in true 3D reconstruction (Fig. 16) [97, 109].

Figure 17 shows a typical PET facility, and Figure 18 shows the maximum intensity projection (MIP) of a typical F-18 FDG whole-body PET acquisition.

*Transformable PET camera (HOTPET)* A high-resolution, flexible transformable PET camera has been developed [110] that can be configured into either a

**Figure 16** Illustration of principles of data acquisition for the proposed axial 3D brain PET camera using the novel design based on 12 camera modules consisting of long scintillation crystals readout on both sides by HPDs shown in Figure 15C [106].

**Figure 18** Maximam intensity projection (MIP) of a typical F-18 FDG whole-body PET acquisition [108].

**Figure 17** Typical PET facility [108].

**Figure 19** Transformable detector ring diameter design with individually rotatable detector modules.

whole-body mode (83-cm detector ring diameter, 13-cm axial field of view (AFOV)), or a brain/breast/axilla (54-cm detector ring diameter, 21-cm AFOV) mode (Figs. 19 and 20). The transformation time is 1.5 h. The camera has 12 rectangular detector modules, of which each has a large detection area (13 cm × 21 cm) and three 168 bismuth BGO detector crystals of $2.7 \times 2.7 \times 18\,mm^3$ with built-in front-end electronics. To improve spatial sampling, the gantry on which the camera is mounted can be rotated 30° with a fine step size of 1°, and the high-speed electronics and detector modules also rotate along with the gantry. The system uses only 924 PMTs by applying a low-cost high-resolution PMT-quadrant-sharing detector design. To

**Figure 20** HOTPET in different configurations. (A) Electronics that can rotate with the gantry, (B) whole-body mode, (C) brain imaging mode, and (D) breast image mode.

compensate for the slower scintillation timing of BGO detectors, the camera is equipped with the high-yield pile-up event recovery (HYPER) front-end electronics. A fast light-emitting diode (LED) cross-reference PMT tuning method is used to maintain the PMT gain balance. The system sensitivity is 4.2% for whole-body and 9.2% for brain/breast/axilla mode measured with Na-22 at the center of the field of view. For brain/breast/axilla modes, the transaxial image resolutions at 0 and 10 cm were found to be 2.7 and 4.0 mm, respectively, while for whole-body mode, the image resolutions were 3.3 and 3.9 mm. The resolution is higher than current commercial PET, especially for brain and breast imaging. The slice thickness resolution ranged from 2.6 to 3.3 mm for the middle seven detector rings in brain/breast/axilla modes. High-quality Hoffman brain phantom images were obtained in both brain and whole-body modes.

*Combined PET/CT and PET/MR* The introduction of dual-modality PET/CT systems in the clinical setting in the late 1990s revolutionized the practice of diagnostic imaging [111]. Combined PET/CT systems have been operational for almost a decade since their inception. The complementarity between the intrinsically aligned anatomic (CT) and functional or metabolic (PET) information provided in a "one-stop shop" and the opportunity to use virtually noise-free CT images for attenuation correction of the PET data has contributed to the success of this technology and its wide adoption by the medical imaging community [112, 113].

On the other hand, combining PET with MRI in a single gantry is technically more challenging owing to the strong magnetic fields. First-generation systems have been developed offering opportunities for integrated structural-functional image in vio [114, 115].

***Quantification and Reconstruction*** In principle, PET images can quantitatively reflect the concentration of the labeled compound in the body as a function of time [116]. To achieve absolute quantification, a number of important corrections need to be applied to the PET data. These include corrections for γ ray attenuation in the tissue, scatter in both the tissue and the detectors, accidental coincidence events (two γ rays from unrelated decays that strike the detector within the coincidence time window), detector dead time, and detector efficiency corrections. Furthermore, the raw PET data simply reflect the activity seen along the line joining each detector pair and therefore must be reconstructed into three-dimensional image volumes using either analytic filtered back-projection techniques or iterative reconstruction algorithms [117].

PET images are displayed on a computer monitor for inspection, allowing the identification of areas of the body with different degrees of uptake of the tracer. Comparisons are made between images obtained at different times after administration. Images are analyzed to obtain quantitative values on the drugs/tracers concentration–time profile in different organs or subregions of organs [12]. Therefore, regions of interest (ROI) are manually outlined in the images to represent targeted regions for analysis. Within these ROIs, the radioactivity concentration is determined for each frame in the sequence, resulting in a time–activity data set, displayed as a *time–activity curve*. The radioactivity is rapidly decaying according to the half-life of the radionuclide, so compensation should be applied for the correction. It is common in the PET field to recalculate radioactivity concentration into *standardized uptake value* (SUV), a dimensionless entity (actually milliliter/gram but with an assumed tissue density of 1 g/mL interpreted as dimensionless; the transmission scan can determine the actual density allowing a correct determination), which compensates for differences in administered radioactivity and body weight.

$$\text{SUV} = \frac{\text{local radioactivity concentration}}{\text{administered radioactivity/body weight}}$$

The time–activity data express the tracer's kinetics in a region and can in turn be used for the assessment of the drug concentration if the study is performed in such a way that tracer and drug are mixed and administered together. In this instance the relationship between cold compound and radioactivity is constant with time, if compensation is made for radioactive decay. Thus, also within each region, the relationship between radioactivity concentration and drug concentration is constant and equal to that between administered radioactivity and administered drug.

$$\text{Drug concentration} = \text{SUV} \times \left(\frac{\text{administered drug}}{\text{body weight}}\right)$$

For example, in a coinjection study, the subject of 75 kg was given 300 MBq-labeled compound mixed with 100 mg cold compound. The PET study measured an SUV in the brain of 1.2. This means the drug concentration the brain was $1.2 \times (100/75)$ mg/kg = 1.6 mg/kg = 1.6 μg/g.

***Application of PET in Drug Development*** General speaking, for drug development, PET can be used to: (1) provide in vivo biological characterization of disease (Imaging samples the entire cancer. It can quantitatively measure tumor heterogeneity in space and time. Serial assay is possible with imaging [118]). (2) Titrate drug to disease target in tissue for accurate dosing using a labeled form of the drug. (3) Provide pharmacodynamic and pharmacokinetic characterization of drugs and probes. (4) Determine whether the drug properly modified the biological process of disease or restored a normal process affected by disease [88].

### 5.4 Human Microdosing PET

PET microdosing studies are designed to determine the plasma and tissue pharmacokinetic profile of an investigational drug in vivo. Such an approach is also referred to as "pharmacokinetic imaging" [119, 120]. Direct assessment of the pharmacokinetics of a candidate drug in the target tissue, as provided by PET microdosing, has not been feasible using any other method. The concept of PET microdosing includes assessment of safety aspects, preclinical validations, and performance and analysis of human trials. In PET microdosing studies, trace amounts of a drug labeled with a short-lived positron emitter, such as carbon-11 or fluorine-18, are administered, usually by intravenous injection (oral administration is uncommon because of the need for high gastrointestinal dose rates). Dynamic PET images of various organ systems are subsequently recorded, and arterial or venous blood sampling is simultaneously performed to quantify the radiolabeled drug and its metabolites in plasma, using chromatographic methods such as high-performance liquid chromatography. In "receptor occupancy studies" (not microdosing studies, as they involve the administration of therapeutic doses of drugs that fail to fulfill the key requisite of microdosing studies), which aims to describe the interaction of a drug molecule with its pharmacodynamic target (e.g., receptor, transporter protein, or enzyme) by coadministering a validated PET tracer with different doses of the unlabeled drug under investigation. The level of

binding site occupancy induced by the unlabeled drug can then be monitored via PET imaging.

PET microdosing studies are gaining increasing importance in anticancer drug development. They are useful in understanding drug distribution in tumor tissue and can thus widen the narrow therapeutic index of cytotoxic therapy. Furthermore, the concept of radiolabeling anticancer drugs is appealing in view of the rising emphasis on personalized medicine. PET enables the measurement of pharmacokinetic parameters in individual patients in a noninvasive manner, prior to initiating full-dose treatment [90].

The radiation exposure of one PET scan is of approximately the same order as annual exposure from natural background irradiation (1–2 mSv/year). The radiation exposure of healthy volunteers and patients (5–10) in clinical studies with PET tracers is not uniformly regulated across different countries. In some countries, such as in the United States, there are clearly defined radiation dose limits, which might make whole-body dosimetry estimations mandatory in, for example, nonhuman primates, prior to initiating a phase 0 PET microdosing study. In other countries, however, no formal radiation dose limits are set for clinical research protocols, and risk-benefit evaluations are assessed on a case-by-case basis by local investigational review boards and/or competent authorities.

In contrast to AMS microdosing, PET microdosing is usually conducted subject by subject. There are two approaches to PET microdosing. First, the use of an isotope-labeled ligand, which is displaced by the drug substance under investigation. This is particularly useful for drugs designed to treat central nervous system disorders and establishes not only whether the drug reaches the brain, but whether it binds to the specific receptor it is designed to target. The rate of in vivo synthesis of dopamine, for example, can be investigated using $^{11}$C-dihydroxyphenylalanine ($^{11}$CDOPA) [121]. Therapeutic dose effects of a drug can be studied using labeled precursors in a metabolic pathway of interest. For example, the glucose analog $^{18}$FDG can be used to study effects on glucose metabolism. Similarly to glucose, $^{18}$FDG is metabolized to FDG-6-phosphate, which is then trapped in the cells. The rate of glucose uptake is, therefore, equivalent to the rate of glucose metabolism. Protein synthesis can be studied by following the uptake of $^{11}$C-tyrosine, whereas oxygen consumption and water uptake can be studied using $H_2{}^{18}O$. The selective effects of candidate drugs on metabolism in selective tissues—tumours, for example—can assist in candidate selection [93].

Alternatively, the drug itself can be labeled and its ability to reach target tissues can then be studied. Although feasible, this approach is used less frequently because of the difficulties of chemically synthesizing the radiolabeled drug [8].

What is appealing about the use of PET microdosing for assessing the pharmacokinetics of a compound is that the pattern of anatomical distribution of a radiolabeled drug might provide the first evidence of the interaction of the drug with its pharmacological target. The ability of PET to visualize drug–target site interactions is related to the fact that PET tracers are manufactured at high specific activities, implying that the amount of unlabeled carrier is low. The tissue concentration levels achieved may therefore be in the same range as the affinity of a drug (i.e., $K_i$, $K_d$) for its pharmacological target. This is of particular relevance as there is an increasing tendency to develop therapeutic drugs with high target site binding affinities (in the nanomolar or subnanomolar range). PET imaging with drugs labeled at high specific activity, therefore, has the potential to demonstrate whether a drug reaches its therapeutic target or not. It is believed that CNS (central nervous system) agents are particularly eligible for PET microdosing studies [90]. The human BBB (blood–brain barrier) represents a unique and selective filter for insufficiently lipophilic drugs [122], which preclinical models sometimes fail to predict. What PET cannot provide is chemical resolution, as the parent drug and its metabolites produce the same signal. Therefore, PET imaging should preferably be performed with compounds that are metabolically stable or whose metabolites are not taken up or retained in the tissue being investigated. The BBB impedes radiolabeled hydrophilic drug metabolites from penetrating into brain tissue and thus increases the signal-to-noise ratio of PET imaging.

***Added Value of PET Microdosing in Drug Development***

PET using trace amounts of radiolabeled drugs can answer questions that are crucial for clinical drug development such as: Does the drug reach its target organ? If so, does it attain functionally and therapeutically important concentrations? Is the residence time of the drug in its target tissue sufficient? Is there any accumulation in other organs that might affect the safety of the candidate drug? Moreover, by providing human pharmacokinetic data, even before extensive preclinical testing has been started, PET microdosing can provide guidance with respect to the selection of appropriate animal species for its detailed pharmacological and toxicological evaluation. The availability of such information at the interface of preclinical and clinical drug research helps to save time and money, as candidate drugs with unfavorable pharmacokinetic properties can be discarded before they enter into considerably more expensive phase I/II clinical trials. On the other hand,

preclinical PET could be a good method for assessing the dose linearity of a drug—an issue that is often discussed as a limitation of the microdosing concept [35, 90].

***Dose Linearity*** However, the PET method allows the recording of tissue kinetics and plasma kinetics at the same time and, therefore, allows a modeling of this relationship. The exchange of drug between tissue and plasma is usually little affected by dose and more conserved in-between species [12]. So, dose linearity means that the tissue-to-plasma relationship is unaffected by dose. In order to allow a correct extrapolation from a PET microdosing study, it is necessary to make an assessment of dose linearity. Going from a tracer-alone administration to a therapeutic dose mixed with the radiolabeled counterpart. Plasma kinetics and organ kinetics are recorded and additionally the fraction of nonmetabolized tracer in plasma is measured. With dose linearity, the time–activity data of each of the doses would be the same.

***Costs*** PET is a complicated and relatively costly technique that requires considerable infrastructure. In addition to a PET scanner, a cyclotron and radiochemistry facilities are necessary for the manufacture of the short-lived radiotracers [90]. PET studies can, if well planned in the drug development process, be very cost effective, although the price of PET may seem high. A very rough estimate of the costs of this PET microdosing package suggest an overall cost of about $300,000, subdivided into chemistry development $40,000, safety evaluation $50,000, preclinical validation $50,000, PET studies $110,000, and CRO (clinical research organization) costs $50,000 [12]. The number of PET centers, however, is continuously increasing; there are currently more than 500 facilities worldwide. The rising number of industry-owned and joint industry–academic PET centers emphasizes the increasing importance of this tool for drug development.

Table 5 presents the comparison of three analytical techniques used in human microdosing studies. An obvious advantage of PET microdosing compared with AMS is that it is able to provide invaluable information on drug distribution and kinetics in all organs of the human body, most importantly the brain [90]. AMS has, in some instances, been used to quantify drug concentration in peripheral body compartments by means of tissue biopsy. However, it is obvious that such samples cannot be collected from all organs of the human body. Moreover, repeated biopsy sampling for assessment of drug concentrations in tissue over time is not feasible for ethical reasons. On the other hand, because of the abundance of carbon, the majority of PET microdosing experiments have relied on [$^{11}$C]-labeled tracer molecules despite the rather impracticable half-life of this isotope [12]. Thus, one of the limitations of PET microdosing studies is that typical examination times for a [$^{11}$C]-labeled drug last only about 1.5–2 h. Drugs with a terminal plasma elimination half-life that is longer than the sampling duration are therefore considered to be inappropriate for plasma pharmacokinetic evaluation in a PET study [123]. For AMS, the fate of a [$^{14}$C]-labeled drug in plasma can be followed for much longer periods (several days to months). It thus becomes evident that if a drug of interest can be labeled with both a positron-emitting radionuclide, such as carbon-11, and the long-lived β-emitter carbon-14, then combined analysis by

**TABLE 5 Comparison of PET, AMS, and LC-MS/MS in Microdosing Studies**

| PET | AMS | LC-MS/MS |
|---|---|---|
| Highly sensitive ($10^{-32}$ to $10^{-18}$ g) | | Sensitive ($10^{-12}$ g) |
| Plasma and tissue pharmacokinetics | Plasma pharmacokinetics only (e.g., urine, cerebrospinal fluid, biopsy when accessible, feces) | |
| Relatively low radiation burden | Very low radiation burden | No radiation burden |
| Radiolabeled drug required | | No radiolabeled drug required |
| $\beta^+$-emitting, short-lived radioisotopes | $\beta^+$-emitting, long-lived radioisotopes | |
| No chemical separation of tissue signal | Chemical separation of drug-related material in plasma. Metabolites quantifiable without analytical standards | Chemical separation of drug-related material in plasma; structural elucidation of drug metabolites but quantification extremely difficult without analytical standards |
| Intravenous administration only | Intravenous and oral administration | |
| Limited sampling periods owing to short radioactive half-lives | Sampling period is essentially unlimited and depends only on the plasma clearance of drug | |
| Relatively high costs, limited availability | | Low costs, better availability |
| Analysis needs to be done on-site | Analysis can be outsourced | |

both PET and AMS could provide more precise tissue and plasma pharmacokinetic data than either technique alone [90].

## 6 EXAMPLES OF HUMAN MICRODOSING

### 6.1 First Microdosing Data

The data were acquired incidentally when xenobiotics with deoxyribonucleic acid (DNA) binding potential were administrated to laboratory animals and humans at environmental relevant doses (around 1990) [124]. AMS was used as the analytical technique. In general, the DNA-binding data were scalable between the doses [125], and it was also shown that the animal models were not necessarily good predictors for humans [126, 127].

### 6.2 Prediction of Pharmacokinetics of a Pharmacologic Dose from a Microdose

Will the pharmacokinetics be linear between a microdose and a therapeutic dose? It is largely because of this question that the microsdoing concept is a controversial subject. Even though that perfect linearity kinetics might not be necessary in order to make a selection for a series of drug candidates. Hopefully, with the accumulating knowledge surrounding the microdosing concept, we can use microdosing intelligently as one of the tools in the toolbox for drug candidate selection [128–131].

The first (and most up-to-date) comprehensive human study comparing microdose and therapeutic dose pharmacokinetics was completed in 2006 [35, 124]. This study is under the support of the Consortium for Resourcing and Evaluating AMS Microdosing (CREAM). The consortium comprised Xceleron, Pharma Bio-Research, Servier, Roche, Schering AG, and Eli Lilly. This study contributes to solving the paradox that many pharmaceutical companies show an interest in microdosing but are hesitant to test the concept (or publish their microdosing data since the studies are conducted at the critical stage in drug development when commercial confidentiality is paramount). The conclusion for this study is that human microdosing offers the potential to aid in early drug candidate selection. Views from the other side of the aisle stated that only for two of the five drugs was the pharmacokinetics following the microdose in agreement with that for the therapeutic dose, when both were administered by the same route. For another two drugs, even with the ultrasensitive AMS analytical method, plasma concentrations following an oral microdose were undetectable at all sampling times; and in one additional case, the terminal half-life for the microdose was more than fivefold longer than that for the therapeutic dose, which was attributed to saturable tissue binding at the higher dose. Therefore, the results highlight the limitations of microdose studies in predicting pharmacokinetics at therapeutic doses in a significant proportion of the drugs tested and thus the risk of making the wrong decision when based on microdose data [3]. Precisely due to this kind of debate, more knowledge around human microdosing study is welcome [128–131].

Each compound was selected to represent a situation in which *prediction* of human pharmacokinetics from nonclinical data *might* be considered *problematic*. There, a total of 5 compounds of which 4 are marketed drugs (warfarin, diazepam, miazolam, and erythromycin) and 1 drug (ZK253 by Schering) was rejected during development because of inadequate PK characteristics. AMS was used to quantify the low plasma concentrations anticipated after microdose administration. The volunteers include 30 subject, 24 men (18–55 years old) and 6 women (45–80 year old).

Midazolam was tested since it is a cytochrome P450 (CY)3A4 substrate that undergoes extensive first-pass metabolism that makes the pharmacokinetics difficult to predict using in vitro and animal methods. Another reason were that there were suggestions that the pharmacokinetics of high-clearance drugs, such as midazolam, are unlikely to be linear from a microdose to a therapeutic dose due to possible enzyme saturation effects [132]. The result in Figure 21 shows linearity. Results of midazolam showed predicative bioavialability due to first pass and predictive PK within a fator of 2.

Diazepam, a basic drug that is extensively distributed, also exhibited linear kinetics between a microdose and therapeutic dose (Fig. 21). It showed predictive PK.

ZK253 is interesting, which had an approximate twofold difference in half-life and clearance between microdose and therapeutic dose that resulted in the same volume of distribution for both doses, a better view of the pharmacokinetic linearity was obtained by looking at the pharmacokinetic curves (Fig. 21). Results of ZK253 showed low oral bioavailability and predictive PK within a factor of 2.

The case for warfarin is special. The plasma concentration for the microdose dropped more sharply before displaying a longer terminal phase comparing to its therapeutic dose (Fig. 21). However, estimates of clearance were similar (Table 6). Microdose data would have been useful in predicting clearance for a therapeutic dose. The situation probably is due to the fact the warfarin has a low-capacity, high-affinity binding site along with its small volume of distribution so that the biding site probably saturates at the higher dose, which has

**Figure 21** Plasma concentrations after dosing. Data are normalized to a 1-mg dose. Three drugs (midazolam, diazepam, and ZK253) demonstrated dose linearity through these overlapping pharcokinetic curves, while warfarin did not due to its a low-capacity high-affinity binding site along with its small volume of distribution [124].

**TABLE 6 Summary of Pharmacokinetic Parameters Achieved for a Microdose and a Therapeutic Dose for Four Drugs**

| Drug | Dose | Route | $t_{1/2}$ (h) | CL (L/h) | V (L) | $AUC_{\infty}$[c] (ng · h/mL) | $C_{max}$ (ng) | F (%) |
|---|---|---|---|---|---|---|---|---|
| Warfarin | 100 µg | O | 274 | 0.17 | 67.3 | 571 | 5.04 | |
| | 5 mg | O | 48.6 | 0.26 | 17.9 | 20801 | 493 | |
| ZK253 | 100 µg | IV | 56.2 | 14.8 | 1207 | 7.15 | 1.52 | <1% |
| | 50 mg[a] | O | 31.1 | 29.5 | 1257 | | | <1% |
| Diazepam | 100 µg | IV | 45.1 | 1.38 | 90.1 | 65.5 | 4.70 | |
| | 10 mg | IV | 35.7 | 1.30 | 123 | 5577 | 322 | |
| Midazolam | 100 µg | IV | 4.87 | 20.4 | 75.1 | 4.68 | 2.97 | 22.1 |
| | 7.5 mg | O | 3.31 | 27.7[b] | 77[b] | 87.0 | 34.0 | 22.8 |

[a]From previous phasel I study (intravenous and oral routes of administration).
[b]From literature [25, 26].
[c]$AUC_{\infty}$ = area under the concentration–time curve to infinity; CI = clearance; $C_{max}$ = maximum drug concentration; $F$ = bioavailability; IV = intravenous routes of administration; O = oral; $t_{1/2}$ = half-life; V = volume of distribution.

*Source*: From ref. 124.

been observed for wafarin in rat [133]. Therefore, some caution would be justified for drugs similar to warfarin if using microdosing for candidate selection. Therefore, the results of warfarin showed predictive clearance (CL) but not predictive distribution from microdosing study. The lesson learned from this study is to be cautious of drugs that exhibit high-affinity binding to low-capacity biding site. Indications are that there are no specific reasons why drugs with high protein binding will not be predictive.

The study also included the P-glycoprotein substrate erythromycin (an *acid-labile drug*). Due to gastric lability of the labeled drug, nomeaningful comparison could be made between microdose and the therapeutic dose [36]. The study highlights the need to evaluate *drug stability* in gastric and intestinal fluids when one is con-

templating performing oral microdosing studies. Acid-labile drugs dosed orally have to be protected from stomach acid. Indications are that there are no specific reasons why P-glycoprotein (Pg-p) substrates will not be predictive.

### 6.3 PET Microdosing

A PET microdosing study [92] has been carried out with an investigational, carbon-11-labeled antiamyloid drug, 1,1-methylene-di-(2-naphthol) (ST1859) with three healthy volunteers and six patients with Alzheimer's disease. The study aimed to assess the distribution and local tissue pharmacokinetics of the study drug in its target organ, the human brain. Before PET studies were performed in humans, the toxicologic characteristics of ST1859 were investigated by an extended single-dose toxicity study according to guidelines of the FDA and European Medicines Agency, which are relevant for clinical trials with a single microdose.

After intravenous bolus injection of 341 ± 21 MBq [$^{11}$C]ST1859 (containing <11.4 nmol of unlabeled ST1859), peripheral metabolism was rapid, with less than 20% of total plasma radioactivity being in the form of unchanged parent drug at 10 min after administration. In both the control and patient groups, uptake of radioactivity into the brain was relatively fast (time to reach maximum concentration, 9–17 min) and pronounced [maximum concentration (standardized uptake value), 1.3–2.2] (Table 7, Fig. 22). In both healthy volunteers and patients, there was a rather uniform distribution of radioactivity in the brain (Fig. 23), including both amyloid-β–rich and amyloid-β–poor regions, with slow washout of radioactivity (half-life, 82–185 min).

In summary, these data provide important information on the blood–brain barrier penetration and metabolism of an investigational antiamyloid drug and suggest that the PET microdosing approach is a useful method to describe the target organ pharmacokinetics of radiolabeled drugs in humans.

### 6.4 List of Human Microdosing Studies in Order of Published Date

***1975*** FDA Radioactive Drug Research Committee allowed "microdosing" study with certain restriction.

***1990*** First microdosing data (AMS studies of environmental carcinogens $^{14}$C-MelQx by binding to DNA) [125].

***1996*** The antidepressant, BMS-181101, one of a select number of investigational CNS pharmaceuticals, was labeled with carbon-11 and administered to healthy volunteers at a microdose level to determine drug distribution in brain tissue [134]. Further clinical development of BMS-181101 was abandoned because PET imaging, using both high and low specific activity radiotracers, failed to reveal saturable target-site-specific binding of this investigational drug [135]. The PET microdosing approach selected in the case of BMS-181101 was judicious, as insufficient or fluctuating tissue concentrations of the investigational drug might considerably decrease occupancy of binding sites and affect therapy outcome [90].

***2001*** In an anticancer microdosing study [136], PET imaging was used to determine tumor tissue distribution of the [$^{11}$C]-labeled topoisomerase I/II inhibitor *N*-[(dimethylamino)ethyl]acridine-4-carboxamide, at one-thousandth of the phase I clinical trial starting dose. This study formed part of a series of studies examining novel anticancer agents designed around the use of PET in early clinical drug development [137]. In a more recent study using the same radiotracer, it was demonstrated

**TABLE 7 Pharmacokinetic Parameters of [$^{11}$C]ST1859 in Venous Plasma and Brain[a,b]**

| | Venous Plasma | | Isocortex | | Basal Frontal Lobe | | Pons | |

[a]Data represent mean ± SD pharmacokinetic parameters of radioactivity in venous plasma (metabolite-corrected) and three selected brain regions after intravenous injection of [$^{11}$C]ST1859 into control subjects ($n$ = 3) and AD patients ($n$ = 6).
[b]ST1859. 1.1′-Methylene-di-(2-naphthol): AD, Alzheimer's disease; $C_{max}$, maximum concentration; SUV, standardized uptake value; $t_{max}$, time to reach maximum concentration; $t_{1/2}$, elimination half-life; $AUC_{O-1}$, area under time–activity curve from time 0 to last observation point.
[c]Radinactivity concentrations (in kilobecquerels per gram of tissue) were normalized to the injected radiotracer amount per body weight and expressed as dimensionless SUV.
[d]The unit for AUC (minutes) is different from conventional units because the concentration is expressed as dimensionless SUV.

**Figure 22** Time–activity curves measured in three different brain regions of interest [isocortex (A), basal frontal lobe (B), and pons (C)] and one extracerebral region of interest [left lateral eye muscle (D)] after intravenous administration of [$^{11}$C]ST1859 to three healthy volunteers and six patients.

that tracer studies performed with plasma levels that were severalfold lower than the Michaelis–Menten constant ($K_m$) for metabolizing enzymes could still provide valuable information on drug clearance from plasma for the entire concentration range [35, 123].

***2003*** 1. An orally active $\alpha_{1A}$-adrenoceptor antagonist for the treatment of benign prostatic hyperplasia was administered to six healthy male volunteers with doses of 5, 50, and a pharmacological dose of 500 μg. $^{14}$C levels were measured in plasma by AMS, and the plasma pharmacokinetics was demonstrated to be linear between doses [8].

2. PET microdosing was first introduced [12, 90].

***2004*** 1. U.S. FDA Critical Path Initiative [23].

2. The microdose European Medicines Agency position paper [39].

3. (Microdosing in dogs) AMS was used to study the pharmacokinetics and disposition in dogs of a preclinical drug candidate (7-deaza-2′-C-methyladenosine) after oral and intravenous administration [138]. The primary objective of this study was to *examine* whether the drug displayed *linear kinetics* across subpharmacological (microdose) and pharmacological dose ranges in an animal model *before initiation of a human microdose study.* The AMS-derived disposition properties of the drug were comparable to data obtained via conventional techniques such as (LC-MS/MS) and liquid scintillation counting analyses (confirmed the use of AMS). The drug displayed multiphasic kinetics and exhibited low plasma clearance (5.8 mL/min/kg), a long terminal elimination half-life (17.5 h), and high oral bioavailability (103%). This study thus provided the first description of the full pharmacokinetic profile of a drug candidate assessed under subpharmacological and pharmacological doses. The pharmacokinetics in the dog appears to be linear across this 50-fold dose range.

***2005*** 1. A successful use of AMS in the generation of valuable pharmacokinetic information for nelfinavir in an absolute bioavailability study in healthy volunteers

**Figure 23** Transaxial magnetic resonance–coregistered PET summation images recorded from 20 to 90 min after intravenous injection of [$^{11}$C]ST1859 into one control subject (HV 1) (*left*) and one AD patient (patient 9) (*right*). The *lower row* shows the same PET images with the transparency of the superimposed magnetic resonance scan set to 50%. The radioactivity concentration is normalized for injected radioactivity per body weight and expressed as the standardized uptake values (SUV).

that included the administration of an IV microdose of $^{14}$C-nelfinavir [139]. Because the moderate oral bioavailability of nelfinavir is due primarily to metabolic reasons, the results from this study indicated that traditional formulation improvement aimed at better gastrointestinal absorption would be unlikely to improve the oral bioavailability of nelfinavir in chronic treatment. This allowed the sponsor to make an appropriate cost–benefit decision and avoid allocating significant pharmaceutical science resources in developing a new oral formulation.

The author also concluded that human absolute bioavailability studies with administration of an IV microdose simultaneously with a conventional pharmacological oral dose of the same drug can yield important information about the gastrointestinal absorption versus first-pass metabolic turnover. Ultrasensitive and robust analytical techniques such as AMS can measure parent drug and metabolite concentrations with sufficient precision to characterize the full pharmacokinetic profile of a microdose. Administration of microdoses of $^{14}$C-labeled drugs, in conjunction with the sensitivity of the AMS approach, can reduce potential safety issues arising when dosing radioactivity to humans and prevent the need for formulation of high IV doses for absolute bioavailability studies.

2. (News Report [140]) Animal tests were made a legal requirement following the thalidomide tragedy 40 years ago, in the hope of preventing another such disaster. But have they lived up to their promise? Recently withdrawn arthritis drug Vioxx was safe and even beneficial to animal hearts but caused as many as 140,000 heart attacks and strokes in people—the biggest drug catastrophe in history. Shockingly, adverse reactions to prescription medicines (all tested for safety on animals) are now the fourth leading cause of death in the western world: killing over 10,000 people a year in the United Kingdom and costing the National Health Service (NHS) £466 million. New human-based safety tests before and during clinical trials (such as microdosing) could prevent many of these deaths.

3. First Human Data on Next Generation of Renin Inhibitors [141]. SPP630 and SPP635, compounds with low nanomolar potency being evaluated by Speedel (Basel, Switzerland, and Bridgewater, New Jersey) have been tested in microdosing studies with human volunteers and in preclinical studies with transgenic rats that express the human genes for renin and angiotensinogen. These studies show that these renin inhibitors demonstrated bioavailability in humans to 30% and in rats of 70–90%; have a half-life of more than 30 h in humans, making them suitable for once-daily dosing; show larger tissue distribution than previous renin inhibitors; and not only reduce blood pressure in transgenic rats over 24 h, but also slow the progression of renal damage after oral treatment. Both SPP630 and SPP635, together with other compounds from the SPP600 series, will be evaluated in toxicology studies before a decision is made about which compound(s) will continue in classic phase I studies with single-ascending and multiple-ascending doses.

***2006*** 1. U.S. FDA expIND guidance [40].

2. January 31, 2006, Xceleron news announcement regarding he European Union Microdose AMS Partnership Programme (EUMAPP), "This programme follows on from the successful CREAM trial and will add *7 more drugs* to the growing portfolio of compounds tested by Xceleron," said Professor Colin Garner, Xceleron's CEO. "Theorists can think of a number of situations whereby the predictivity of microdosing might be questioned, however in practice and taking into account many 'difficult' cases Xceleron has shown that microdosing should have an 80 per cent plus level of predictivity", said the spokesperson.

3. A feasibility study with conventional LC-MS/MS technology for oral microdosing assessment in rats (three drugs were studied) [132]. It was demonstrate that pharmacokinetics can be readily characterized by LC-MS/MS at microdose of 1 μg/kg for nonlabeled

drugs fluconazole and tolbutamide in rats, and, hence, LC-MS/MS should be adequate in human microdosing studies. The studies also exhibit linearity in exposure between the microdose and ≥1000-fold higher doses in rats for these drugs, which are known to show linear dose-exposure relationship in the clinic, further substantiating the potential utility of LC-MS/MS in defining pharmacokinetics from the microdose of drugs. These data should increase confidence on the use of LC-MS/MS in microdose pharmacokinetics studies of new chemical entities in humans. Application of this approach is also described for an investigational compound MLNX where the pharmacokinetics in rats were determined to be nonlinear, suggesting that MLNX pharmacokinetics at microdoses in humans also might not reflect those at the therapeutic doses.

4. The first (and most up-to-date) comprehensive human study comparing microdose and therapeutic dose pharmacokinetics was completed under the support of the Consortium for Resourcing and Evaluating AMS Microdosing (CREAM) [35, 124].

5. A PET microdosing study [92] has been carried out with an investigational antiamyloid drug (ST1859) with three healthy volunteers and six patients with Alzheimer's disease (see PET microdosing example section for details).

***2007*** 1. AMS microdosing study of the pharmacokinetics and metabolism of imatinib in patients on long-term therapy for chronic myelogenous leukemia [142]. This is possibly the first human study involving an anticancer drug that investigates the pharmacokinetic profile of an individual dose under steady-state conditions [32]. Six patients who were receiving imatinib (400 mg/day) as part of their ongoing treatment for chronic myeloid leukemia (CML) received a dose containing a trace quantity (13.6 kBq) of C-14-imatinib. Blood samples were collected from patients before and at various times up to 72 h after administration of the test dose and were processed to provide samples of plasma and peripheral blood lymphocytes (PBL). Samples were analyzed by AMS, with chromatographic separation of parent compound from metabolites. In addition, plasma samples were analyzed by LC/MS. Analysis of the AMS data indicated that imatinib was rapidly absorbed and could be detected in plasma up to 72 h after administration. Imatinib was also detectable in PBL at 24 h after administration of the C-14-labeled dose. Comparison of plasma concentrations determined by AMS with those derived by LC/MS analysis gave similar average estimates of area under plasma concentration time curve ($26 \pm 3$ versus $27 \pm 11\,\mu g/mL \cdot h$), *confirming* the predictability of microdosing study, but with some variation within each individual. The demonstration that AMS can be applied to investigate the pharmacokinetics of a single dose of imatinib in the context of chronic therapy provides a unique opportunity to revisit and reevaluate the drug interaction potential of imatinib at steady state [32]. Similar approaches can also be applied using a radiolabeled intravenous tracer dose of imatinib administered simultaneously with a nonlabeled oral dose [143] to determine absolute bioavailability in individual patients and discriminate between absorption and elimination as a potential cause for the occurrence of pharmacokinetic resistance to imatinib treatment.

2. (Not a microdosing study) PET studies were carried out in three baboons to measure pharmacokinetics in the brain and peripheral organs and to determine the effect of a therapeutic dose of imatinib [144]. Imatinib mesylate (Gleevec) is a well-known drug for treating chronic myeloid leukemia and gastrointestinal stromal tumors. its active ingredient, imatinib ([4-[(4-methyl-l-piperazinyl)methyl]-*N*-[4-methyl-3-[[4-(3-pyridyl)-2-pyrimidinyl]amino]phenyl]benzamide), blocks the activity of several tyrosine kinases. This work labeled imatinib with carbon-11 as a tool for determining the drug distribution and pharmacokinetics of imatinib. The results showed that [N-C-11-methyl]imatinib uptake in the brain is negligible (consistent with P-glycoprotein-mediated efflux); it peaks and clears rapidly from the heart, lungs and spleen. Peak uptake and clearance occur more slowly in the liver and kidneys, followed by accumulation in the gallbladder and urinary bladder. Pretreatment with imatinib did not change uptake in the heart, lungs, kidneys and spleen, and increased uptake in the liver and gallbladder. Therefore, [N-C-11-methyl]imatinib has *potential* for assessing the regional distribution and kinetics of imatinib in the human body to determine whether the drug targets tumors and to identify other organs to which the drug or its labeled metabolites distribute. Paired with tracers such as 2-deoxy-2-[F-18]fluoro-D-glucose ($^{18}$FDG) and 3′-deoxy-3′-[F-18]fluorothymidine ((FLT)-F-18), [N-C-11-methyl]imatinib may be a useful radiotracer for planning chemotherapy, for monitoring response to treatment, and for assessing the role of drug pharmacokinetics in drug resistance.

3. Belgian national guidance for exploratory studies in humans [41].

4. (News report) Microdosing with human tissues [145]. Robert Schmouder, executive director of translational medicine at Novartis, said at a Cambridge Healthtech Institute conference translational medicine that preclinical microdosing studies aimed at gauging the activity of investigational drugs in humans on a metabolic and pharmacokinetic level, commonly referred to as "phase 0" studies, won't predict whether a drug candidate will succeed or fail at higher doses and in broader populations. These studies rely on "a much

smaller dose than you are going to give actually, so you are really restricted in the amount of drug you can give. . . . We see a lot of examples where [microdose studies] don't give you the data that you want to have" before going into clinical development. As a company that has performed between 5 and 10 of the eINDs, Novartis is "still assessing what the utility of the eINDs are," according to Schmouder. However, a different type of service, called Phase Zero and provided by Asterand, relies on human tissues rather than human beings, and may be right up pharma's alley as companies increasingly try to employ predictive technologies to make go/no-go decisions in preclinical studies. Using human tissue samples rather than human beings, Asterand's Phase Zero Drug Discovery Service investigates a drug candidate's efficacy, pharmacology, safety profiling, and metabolism by using a variety of techniques, including gene expression profiling and protein expression profiling. While some in the industry may question the utility of FDA's phase 0 studies, Asterand's version may be more attractive to big pharma, particularly at a time when the industry is embracing R&D strategies that provide greater clarity about the likelihood of a drug candidate's success prior to entering full-fledged clinical development. According to Amanda Woodrooffe of Asterand's department of biochemical pharmacology, *18 out of the top 20 pharma companies, as well as key biotech companies, are using the company's Phase Zero services.* "I think the pharmaceutical industry is really buying into managing risk and helping build confidence that they are making the right decision early on." Asterand's Phase Zero services could be attractive to industry because they allow companies to use human tissue approaches in their early discovery phase to weed out the compounds that have lower chances for success. In this way "the companies can actually focus their budgets on investing in the compounds that are more likely to have success once they do get into the clinic."

According to the FDA, 9 out of 10 compounds fail in the clinic because they were advanced to human subjects based on how they metabolized in animal studies.

5. September 5, 2007, Closing remark by Dr. James H. Doroshow of Nation Cancer Institute workshop on "Phase 0 Trials in Oncologic Drug Development" [146].

Are phase 0 studies feasible? (a) Phase 0 recruitment is feasible but depends on patient altruism and prior physician–patient relationship. (b) Statistical methodology is more challenging in phase 0 trials, which involve novel PD endpoints and a small number of samples. (c) Require additional upfront investment in imaging or assay development, in addition to that needed for standard PK.

In what circumstances are phase 0 studies applicable for early drug development? Phase 0 trials provide the opportunity to develop PD assays measuring target function in tumors in humans. It (a) allows for the assessment of target inhibition as a potential primary endpoint in subsequent trials; (b) develops assay procedures, from tissue acquisition to the assay itself, that actually work in patients in the clinic.

Does conducting a phase 0 study save clinical development time? Critical question is time. It will take years to assess, but likely that imaging-driven PD will make a major impact soon.

6. Results from anonymous Xceleron studies [38]: A basic drug (sleep disorder) showed PK scalability between microdose and therapeutic dose in a 50-fold dose range. A basic drug with long $t_{1/2}$(ca. 100 h, sedative) showed PK scalability between microdose and therapeutic dose in a 1000-fold dose range. A drug with extensive phase II metabolism (analgesic) showed PK scalability between microdose and therapeutic dose in a 50,000-fold dose range. A rennin inhibitor showed PK scalability between microdose and therapeutic dose in a 500-fold dose range. A CNS drug with very short $t_{1/2}$(<1 h) showed PK scalability between microdose and therapeutic dose in a 1250-fold dose range.

***2008*** 1. April 5, 2008. Linear pharmacokinetics was demonstrated between a microdose and the therapeutic dose of the PgP substrate fexofenadine in humans, one of the drugs listed in the EUMAPP studies. It was presented by Prof. Colin Garner, CEO of Xceleron, as a late-breaking abstract at ASCPT Orlando, FL. Fexofenadine has been IV microdosed along with an oral therapeutic dose. The mean oral absolute bioavailability is 33% in contrast to the 11% estimation based on unchanged drug in urine, indicating a higher degree of biliary excretion than originally thought.

2. May 1, 2008, Corcept Therapeutics Incorporated (NASDAQ: CORT) announced that its lead selective GR-II antagonist, CORT 108297, produced promising results in a human microdosing study. "The compound was extremely well absorbed, demonstrated good bioavailability and had a half-life that appears compatible with once-a-day oral dosing in this 'first-in-man' study." Corcept had previously announced its discovery of three series of structurally different compounds that are potent blockers of the cortisol receptor but do not block the progesterone or any of the other steroid receptors in in vitro assays. "These microdosing results increase our confidence that we will be able to develop cortisol antagonists that are not abortifacients." Corcept is studying disease states associated with excess production of cortisol, the "stress" hormone.

In summary, there are 20 drugs of microdosing studies that have been carried out so far (16 in humans, 1 in dogs, 3 in rats), 6 additional drugs of microdosing studies are currently being carried out under the European

Union Microdose AMS Partnership Programme (EUMAPP).

## 7 CONCLUSIONS

Human microdosing study is one type of exploratory phase I investigation supported by both U.S. and European regulatory agencies. Very small subpharmacologic doses of a drug are used in humans to obtain an early assessment of pharmacokinetic properties in humans. This has the potential of reducing the number of preclinical animal studies, essential for conducting early clinical human studies, differentiating between good and bad candidate drugs early, and speeding up the early phases of drug development. Human microdosing is a newly established and still evolving concept, around which knowledge begins to accumulate.

Microdosing depends on the availability of ultrasensitive analytical methods, such as AMS and PET that are able to measure drug and metabolite concentrations in the low pictogram to femotgram range. AMS is used for determining PK data by taking body samples over time, processing the samples in the laboratory and then analyzing their drug content. PET provides primarily PD data through real-time imaging and organ-specific PK data.

Due to the high expenditure and a disappointingly low number of compounds achieving market authorization each year, the pharmaceutical industry has undergone a paradigm shift toward a more mechanistic and predictive scientific model for drug development. AMS and PET microdosing are two of the innovative techniques that were employed for rational selection of drug candidates in the strong drive to improve overall success rates of the drug development process.

## 1 INTRODUCTION

### 1.1 Resistance to Classical Antibiotics

The great success of the pharmaceutical industry in creating new antibiotics over the past four decades has perhaps caused the general public and portions of the scientific community to become complacent about the potential for bacterial resistance. Indeed, antibiotic resistance due to the extensive clinical use of classical antibiotics has become a great concern in recent years to medical practitioners and scientists in the field of infectious disease. For instance, over the past 5 years, the rate of resistance to penicillin and cefotaxime has increased by more than 300 and 1000%, respectively (Fig. 1; http://www.cdc.gov/drugresistance/community/files/ads/resis_an.htm). Classical antibiotics work by inhibiting bacterial cell wall synthesis, protein synthesis, DNA (deoxyribonucleic acid) replication, or by modifying metabolism. Bacteria can resist antibiotics as a result of chromosomal changes (mutation or inductive expression of a latent chromosomal gene) or the exchange of genetic material via plasmids and transposons [1]. Antibiotics are rendered inactive by three major mechanisms: (1) antibiotic inactivation by destruction or modification, (2) prevention of access of the antibiotic to the target, and (3) alteration of the target site of the antibiotic [2]. Bacteria have a remarkable ability to overcome each new reagent synthesized as a potential classical antibiotic. Consequently, the current priority is the development of alternative drugs and/or the isolation of native molecules that would allow the consistent and proper control of pathogen-caused diseases [3]. Ideally, these molecules should be active over a wide range of pathogens, easily produced, and not prone to induce resistance.

### 1.2 Antimicrobial Peptides (AMPs) as Antibiotics

Clearly, the development of a new class of antibiotics with very different modes of action compared to classical antibiotics is urgently required. AMPs have emerged as promising candidates for such required novel therapeutic agents. Although the exact mode of action of AMPs has not been established, it is generally accepted that the cytoplasmic membrane is the main target of many AMPs, whereby peptide accumulation in the membrane causes increased permeability and a loss of barrier function, resulting in the leakage of cytoplasmic components and cell death. The development of resistance to membrane-active peptides whose sole target is the cytoplasmic membrane is thought to be considerably reduced compared with that of many current antibiotics, which have more specific molecular targets [4]. This prediction has been substantiated in several studies [5–7]. However, the major barrier to the use of AMPs as antibiotics is their toxicity or ability to lyse eukaryotic

**Figure 1** Proportion of *S. pneumoniae* clinical isolates resistant to penicillin or cefotaxime from 1991–1998. (Adapted from the Center for Disease Control and Prevention website: http://www.cdc.gov/drugresistance/community/files/ads/resis_an.htm.)

cells, normally expressed as hemolytic activity (toxicity to human red blood cells). This is the main reason thus far preventing their applications as injectable therapeutics.

### 1.3 Distribution of Antimicrobial Peptides

Researchers use the term AMPs to describe gene-encoded, typically relatively short (12–100 amino acids) peptides, which have two unique features: (1) a net positive charge of +2 or greater, owing to an excess of basic amino acids (Lys, Arg) over acidic amino acids (Asp, Glu) and (2) an amphipathic nature [4, 8, 9], which segregates basic and hydrophobic residues. AMPs are found in organisms that are evolutionarily quite distant, ranging from single-cell microorganisms to insects and other invertebrates, plants, amphibians, birds, fish, and mammals, including humans [4]. Recently, such peptides were even reported to exist in human immunodeficiency virus (HIV; lentivirus lytic peptide 1 or LLP-1) [10, 11]. To date, more than 500 AMPs have been discovered [12], and at least 50% were identified in invertebrates, predominantly within insects [13]. AMPs are generally present in those parts of animals that are most likely to be in contact with environmental pathogens, that is, skin, ear, eye, tongue, trachea, lungs, gut, testes, and bone marrow [9]. AMPs have unusually broad spectra of activity, including an ability to kill or neutralize gram-negative and gram-positive bacteria, fungi (including yeasts), parasites (including planaria and nematodes), cancer cells, and even enveloped viruses like HIV and herpes simplex virus [3].

### 1.4 Diversity of Structure of Antimicrobial Peptides

Due to the diversity of these molecules, Koczulla and Bals [14] noted that it is difficult to categorize them in a generally accepted classification, although useful group classifications have been utilized for various reviews of the field [4, 13–24]. Overall, AMPs tend to be linear or cyclic peptides containing α-helical and/or β-sheet structure, together with unstructured sequence and frequently stabilized by disulfide bridges. For the purposes of the present review, we believe the most straightforward grouping of peptides is as follows: (a) α helical (helix, helix with hinge, helical with other secondary structure), (b) β sheet with one or more disulfide bonds, (c) cyclic β sheet, and (d) AMPs with no defined secondary structure. Representative examples of each group are discussed below, with specific structures shown in Figure 2.

***α-Helical AMPs*** As noted by Bulet et al. [16], the family of α-helical linear AMPs is diverse, being found in a variety of invertebrates and vertebrates, and representatives of this family may number several hundred.

*α-Helical AMPs with Uninterrupted Helical Regions* One of the most studied of α-helical AMPs is magainin, specifically magainin 1 and 2, which are linear 23-residue peptides from the African clawed toad *Xenopus laevis* (Table 1; Fig. 2). Two-dimensional nuclear magnetic resonance (2D-NMR) studies have shown that magainin 2 is unstructured in a fully aqueous environment but nearly fully helical in 25% aq. trifluoroethanol (TFE), an α-helix-inducing solvent [25]. Later studies [26] carried out two-dimensional NMR in the presence of detergent micelles, since the resulting peptide-containing micelles are regarded as more reliable for structure determinations than mixed organic solvents. Such studies showed magainin 2 to be fully helical in dodecylphosphocholine (DPC) detergent micelles and aqueous TFE solutions, confirming earlier studies. It is interesting to note that such studies were in contrast to suggestions from other researchers using solid-state NMR and Fourier transform infrared (FTIR) [27] studies that a population of magainin molecules exist in β conformation. Magainin 2, the most thoroughly studied member of the magainin family, has been shown to form pores in the membrane [28, 29]. However, recently, Ulrich and co-workers determined the location and alignment of the α-helical AMP, PGLa, a member of the magainin family, in membranes as monitored by solid-state $^{2}$H-NMR ([30] and references therein). Their very thorough structure studies show that PGLa adopts an α-helical structure upon binding to bilayers and lies flat on the

**Figure 2** Secondary structure representations of select antimicrobial peptides. Helices are colored dark gray, β sheets are light gray, disulfide bonds are off-white strings, and unstructured regions are light gray, with the exception of the gramicidin S structure. For gramicidin S, carbon is colored light gray, nitrogen is medium gray, and oxygen is dark gray. Magainin 2 (PDB code 2MAG) [26]; melittin (PDB code 2MLT) [324]; granulysin (PDB code 1L9L) [78]; lactoferricin (PDB code 1Z6V) [80]; thanatin (PDB code 8TFV) [89]; protegrin 1 (PDB code 1PG1) [90]; human α-defensin 4 (PDB code 1ZMM) [93]; gramicidin S (PDB code 1TK2); circulin B (PDB code 2ERI) [325]; indolicidin (PDB code 1G89) [110]; human β-defensin 3 (PDB code 1KJ6) [87]. Illustrations were prepared using PyMOL [326].

S denotes antibiotic sensitive strain; R denotes antibiotic resistant strain.

membrane surface at a peptide/lipid (P/L) ratio of 1:200 with the lysine side chains pointing up toward the water. They refer to the surface bound state as the S state. However, at higher peptide concentrations (P/L of 1:50), PGLa inserts obliquely into the membrane with a shallow tilt angle of about 125°, which they called the T state [30]. The T state is rationalized in terms of peptide dimers. These authors conclude that PGLa is adsorbed to the membrane surface, which is accompanied by a change in secondary structure from unordered to α helical and that this is a slow process on the NMR time scale. In contrast, when the local peptide concentration on the membrane surface reaches a threshold value, the PGLa switches from an S state to a tilted T state, presumably as a result of dimerization, and this process is faster on the NMR time scale. This study concludes that lysis of membranes by this peptide may occur via a different mechanism and not involve a transmembrane alignment and pore formation as observed for other peptides [30].

Frog skin is a particularly rich source of AMPs, including α-helical AMPs [31–37], of which the dermaseptin S family (8 closely related amphipathic α-helical peptides) represents an excellent example. These peptides are polycationic (Lys-rich), α helical, and amphipathic, with their polar/charged and nonpolar amino acids on opposing faces along the long axis of the helix cylinder and a conserved Trp residue at position 3. A recently identified new member of the dermaseptin S family, the 24-residue dermaseptin S9 (Table 1), is an α-helical peptide with a hydrophobic core and cationic termini (also, there is no Trp residue at position 3) [33]. Circular dichroism (CD) and 2D-NMR demonstrated this peptide to be aggregated in water but showed a monomeric nonamphipathic α-helical conformation (mainly residues 6–21) when stabilized by the addition of TFE [33]. Interestingly, even though the peptide has a continuous stretch of hydrophobic residues (residues 6–15; IWLWVLLMIW), it is still classed as amphipathic: a value of 2.73 for residues 6–15 and 2.66 for residues 6–22 (Table 1), due to the difference in relative nonpolarity of the two faces of the helix.

Histatins are a family of neutral and basic histidine-rich peptides present in human parotid and submandibular secretions [38, 39]. Examination of the solution structure of human salivary 24-residue histatin 5 (Table 1) by 2D-NMR indicated that this peptide is unstructured in aqueous solution at pH 3–8 but prefers a largely α-helical conformation in dimethyl sulfoxide solution [39]. Histatin 5 only contains three major hydrophobes (Y10, F14, and Y24) yet is still amphipathic (a value of 2.26) as a result of relative polarity difference between the two faces of the helix.

Piscidins are the first amphipathic, cationic, AMPs to be found in the mast cells of fish [40–45] (Table 1). Recent solid-state NMR measurements showed that the 22-residue piscidin 1 adopts an amphipathic α-helical conformation at water–membrane interfaces, similar to many other linear AMPs [42]. CD measurements also showed that it was unstructured in water but had a high α-helix content in micelles [40]. This was subsequently confirmed by $^{1}$H-NMR data in water and TFE. The 25-residue AMP, pleurocidin (Table 1), also found in fish [46–48], has also been shown by CD and $^{1}$H-NMR to have a random coil conformation in aqueous solution but assumes an amphipathic, α-helical structure (about 16–25% α helix) in TFE and micelles [48]. Further, from $^{15}$N relaxation studies, the helix is a rigid structure in the latter membrane-mimicking environment [48].

CD experiments performed in different solvents indicated the presence of a significant content of helical structures in organic solvent for the 29-residue AMP, ceratotoxin A, derived from the medfly *Ceratitis capitata* [49, 50]. 2D-NMR in methanol confirmed amphipathic, α-helical behavior for the 8- to 25-residue region of the peptide [50].

*α-Helical AMPs with Interrupted Helical Regions*

Cathelicidins represent a major family of host defense peptides that have been identified in fish, birds, and mammals [51–55], and three chicken cathelicidins (fowlicidins 1–3) have been recently identified [56–58] (Table 1). CD showed that the 26-residue fowlicidin 1 was largely unstructured in aqueous solution but exhibited significant α-helical content (up to 81%) in the presence of TFE or sodium dodecyl sulfate (SDS) [53]. Furthermore, 2D-NMR studies determined that fowlicidin 1 does indeed adopt an α-helical conformation but with a slight kink (or "hinge") induced by glycine (residue 16) close to the center, in addition to a short, flexible unstructured region near the N terminus [53]. It should also be noted that the α helix (residues 8–23) of the peptide is much more hydrophobic and less amphipathic than most of the mammalian cathelicidins [53]. Similar CD and 2D-NMR results were observed for the 27-residue fowlicidin 3, which adopts a predominantly α-helical structure (residues 9–25) with a slight kink (hinge) induced by glycine at position 17 [51].

Melittin (Table 1; Fig. 2) is a much studied 26-residue AMP and is the principal component of honeybee (*Apis mellifera*) venom. CD [56–58] and $^{1}$H-NMR [59] showed that the aqueous melittin monomer has no detectable secondary structure. However, the X-ray structure of tetrameric melittin crystallized from aqueous solution [60], as well as 2D-NMR melittin structures in the presence of methanol [61] and micelles [61–64], all indicate that the molecule consists of two

α-helical segments (residues 2–10 and 13–26) connected by a hinge (residues 11 and 12; threonine and glycine, respectively) to form a bent α-helical rod with the hydrophilic and hydrophobic sides facing opposite directions.

Cecropins represent a family of linear 34- to 39-residue AMPs found in the Cecropia moth [65, 66]. CD studies have indicated that cecropins have a largely random coil conformation in water alone but adopt a mainly α-helical (60–80%) conformation in the presence of membrane-mimicking organic solvents [67]. 2D-NMR studies of the 37-residue cecropin A indicated a similar structure to that of melittin (see above; Fig. 2), that is, two amphipathic α-helical regions (from residues 5 to 21 and from residues 24 to 37), with a hinge region (Gly-Pro) connecting the two helices [68]. A similar structure was assessed by 2D-NMR for 34-residue cecropin B1, a derivative of cecropin B, in a membrane-mimicking environment: two stretches of helices (residues 3–22 and residues 26–33) connected by a hinge region formed by Gly 23 and Pro 24 [69] (Table 5).

It is worth noting that, although cecropins and melittin have a similar conformational design (two helices separated by a hinge region), they have reversed polarity [65]: at neutral pH, the first 21 residues of cecropin A include eight positive and two negative charges, whereas the sequence of residues 22–37 only has a single positive charge; in contrast, the N-terminal domain of 20 amino acids in melittin only has two positive charges but residues 21–26 include four positive charges in a row. Subsequent cecropin/melittin hybrids were designed in an attempt to improve antimicrobial activity while minimizing hemolytic tendencies [70–73] (Table 5). For instance, 2D-NMR studies of a hybrid peptide formed by connecting the first 13 residues of each peptide [CA (1–13) M (1–13) = CAM (1–26)] indicated two α-helices, separated by a flexible hinge section, involving residues 4–12 and 16–26, with the latter helix being much more stable than the former [72]. In contrast, 2D-NMR studies with hybrid CA (1–8) M (1–12) indicated an α-helical structure of about three turns in the melittin domain and a flexible structure with one turn in the cecropin domain, connected by a flexible hinge region [70]. An interesting result arose from 2D-NMR studies of a cecropin/melittin hybrid made up of residues 1–8 of cecropin A and residues 1–18 of melittin [CA (1–8) M (1–18)], which indicated a β-pleated structure in water but a right-handed α-helix conformation in a membrane-mimicking environment [73]. Structural studies have also been carried out on a hybrid peptide derived from combining sequences of magainin (uninterrupted α-helix; Fig. 2) and cecropin A (two α-helices linked by a hinge region). Thus, NMR characterization of residues 1–8 of cecropin A and residues 1–12 of magainin [CA (1–8) MA (1–12)] (Table 5) indicated a hydrophobic $3_{10}$ helix of just two turns combined with one short helix at the N terminus, with a flexible hinge region (Gly-Ile-Gly) in between [70]. These researchers reported "a severely bent structure in the middle of the peptide."

PMAP-23 (pig myeloid antibacterial peptide-23; Table 1) is a 23-residue cathelicidin-derived AMP identified from porcine leukocytes [74, 75]. CD studies indicated that this peptide has no appreciable structure in aqueous buffer but exhibits appreciable α-helical structure in the presence of TFE or micelles [74]. Subsequent NMR elucidation of the peptide indicated an α-helical domain from residues 1–10 and a short α-helix from residues 17–23, these two domains being connected by a flexible region containing two proline residues (PXXP) [74].

Pandinins 1 (44 residues) and 2 (24 residues) (Table 1) are α-helical polycationic AMPs from venom of the scorpion *Pandinus imperator* [76, 77]. Both peptides showed an unordered structure in aqueous solution but considerable α-helicity in the presence of TFE or micelles [76]. One-dimensional and 2D-NMR studies in DPC micelles subsequently showed that, though both peptides are essentially helical, they differ in their overall structure: pandinin 1 consists of two distinct amphipathic α-helices separated by a coil region of higher flexibility incorporating a Pro residue; in contrast, pandinin 2 is composed of a single amphipathic α helix with a predominantly hydrophobic N-terminal sequence [76].

*α-Helical AMPs with Disulfide Bonds* Granulysin (Fig. 2) is a 74-residue basic protein produced by human cytolytic T lymphocytes and natural killer cells [78, 79]. The crystal structure of granulysin revealed a five-helix bundle with two disulfide bonds connecting helices 1 and 5 and 2 and 3 [78]. These authors also noted that the granulysin molecule is a small, hydrophobic core, helical bundle, only two helices thick, and is almost entirely amphipathic.

Lactoferricin is generated by gastric pepsin cleavage of lactoferrin [80–82]. 2D-NMR studies of 49-residue human lactoferricin, LfcinH, in a membrane mimetic solvent indicated an amphipathic helix was present between residues 14 and 29 with the remainder of the molecule being of random coil nature. Disulfide bonds are present between Cys 20 and Cys 37 and Cys 10 and Cys 46 [80]. Interestingly, the peptide is partially folded in aqueous solution, with a helical region from Pro 15 to Thr 18 and a coiled backbone to Gln 24, a turn, and then an antiparallel alignment for the remaining sequence of the peptide [80]. These authors also noted

the absence in the peptide solution structure of well-defined β structure, in addition to the helical region, reported for the intact protein crystal structure.

Defensins are small (3–5 kDa) cationic proteins with molecules stabilized by several (usually 3) disulfide bonds [83, 84] and are classified into 2 categories, α and β defensins, based on the arrangement of the disulfide bridges [85, 86]. NMR analysis of solution structures of the 3 human β defensins all exhibit similar mixed conformation tertiary structures, that is, a short helical segment preceding a 3-stranded antiparallel β sheet [87]. For the 45-residue human β-defensin 3 (HBD3) (Fig. 2), disordered structure of the first 6 residues is followed by the short helical segment of residues 10–14 packed against one face of the β-sheet, with the 3 β strands being formed by residues 17–19, 27–31, and 39–43 [87]. Disulfide bonds are present between Cys 23 and Cys 41, Cys 11 and Cys 40, and Cys 18 and Cys 33.

***β-Sheet AMPs with One or More Disulfide Bonds*** Thanatin is a 21-residue peptide that appears in the hemipteran insect *Podisus maculiventris* [88, 89]. 2D-NMR demonstrated a well-defined antiparallel β-sheet structure in water from residue 8 to the C terminus, including the single disulfide bridge between Cys 11 and Cys 18 (Fig. 2). The 2-stranded β-sheet, involving residues 8–12 and residues 17–21, is slightly twisted, with the 2 strands connected by a standard β–β hairpin turn [89].

Protegrins are a family of peptides isolated from porcine leukocytes [90–92] and composed of 16–18 residues, including 4 Cys residues forming 2 disulfide linkages [91]. 2D-NMR studies of the 18-residue protegrin 1 demonstrated a well-defined structure in solution composed mainly of a two-stranded antiparallel β-sheet (residues 4–8 and 13–17) with strands connected by a β-turn [90] (Fig. 2). Disulfide bridges are formed between Cys 6 and Cys 15 and Cys 8 and Cys 13.

Crystal structures of human α-defensins HNP4 (Fig. 2; 34-residue human α-defensin 4), HD5, and HD6 have shown that their tertiary structures are quite similar, that is, 3 β-strands arranged in antiparallel β sheet, a β-hairpin formed by strands β2 and β3, a 7- to 8-residue long loop connecting β1 and β2, and 2 termini (1–4 residues) located close to each other [93]. Three disulfide bridges also serve to stabilize the final conformation of the peptides.

***Cyclic β-Sheet AMPs*** Gramicidin S (GS) (Fig. 2) is a cationic cyclic and amphipathic decapeptide from *Bacillus brevis*. The structure of GS is known from X-ray crystallography [94] as well as $^{1}$H-NMR studies in various solvents [95, 96]: It has an antiparallel β-sheet conformation with a 2-fold symmetry, where 2 equivalent short strands are connected by β-turns consisting of D-Phe and Pro residues. Solid-state $^{19}$F-NMR was also used to study the membrane-bound structure of a $^{19}$F-labeled GS analog [97]. Such studies indicated that the analog is aligned symmetrically with respect to the membrane normal, that is, with its cyclic β-sheet backbone lying flat in the plane of the bilayer, consistent with its amphipathic character.

Circulin A and circulin B (Fig. 2) (CirA, CirB), cyclopsychotride (Cpt), and kalata are large end-to-end cyclic peptides of 29–31 amino acids from plants of the Rubiacease family [98–101]. As a group, these peptides, which contain 6 Cys residues, are reported to be the largest cyclic peptides found in nature [102]. In addition to their cyclic nature, these peptides all exhibit a cystine knot motif in their disulfide connectivity [100, 102–106], characterized by 1 disulfide bond threading through the other 2 to give a knotted motif. 2D-NMR of kalata and CirA determined that they are compact, fairly rigid structures exhibiting a global fold of distorted triple-stranded β-sheets [100, 103]. The rigidity is a result of the peptide backbone being extensively folded back on itself, as well as the cross-bracing of the disulfide bonds.

***AMPs with No Defined Secondary Structure*** Most AMP structures determined to date have included α-helical peptides and β-sheet peptides (including cyclic peptides), with few structures having been determined for other classes of cationic peptides such as extended peptides with no appreciable secondary structure. Tritrpticin is a member of the cathelicidin family and is a 13-residue peptide with 3 consecutive Trp residues (unique for AMPs), as well as 2 Pro and 4 Arg residues [107]. 2D-NMR of the peptide bound to a membrane mimetic indicates that it forms 2 adjacent turns around the 2 Pro residues, that is, a distinct fold for peptide–membrane interaction [108]. The first turn involves residues 4–7, followed by a $3_{10}$-helical turn involving residues 8–11. In addition, the hydrophobic residues are clustered together and separated from the basic Arg residues, thus resulting in an amphipathic structure.

Unlike tritrpticin, which only has a relatively weak antimicrobial activity [108], indolicidin (from bovine neutrophils [109]) has a broad activity spectrum [110, 111]. The 13-residue peptide contains the highest Trp fraction (5 out of 13 residues; 39%) ever observed for a protein sequence. The structure of indolicidin (Fig. 2) was determined using NMR methods and was shown to have a unique membrane-associated peptide structure [110], in contrast to unordered structure in aqueous solution [112]. Thus, the backbone structure, when bound to phospholipid vesicles, was extended and well-defined between residues 3 and 11, with 2 half turns at residues Lys 5 and Trp 8 (Fig. 2). The peptide had a

central hydrophobic core composed of Pro and Trp, bracketed by positively charged regions near the termini. With one exception, the Trp side chains folded flat against the peptide backbone, giving the molecule a wedge shape (Fig. 2).

### 1.5 Target Diversity of Antimicrobial Peptides

In addition to membrane permeabilization and cell lysis, several intracellular mechanisms have been suggested in recent years to explain AMP activity. Indirect evidence of nonmembrane targets consists of differential antimicrobial activity of select all-D versus all-L peptide enantiomers. AMPs kill by membrane pore formation function irrespective of chiral form. However, studies of D-apidaecin showed significant reduction in *Escherichia coli* inhibitory activity compared to the L-enantiomer and indicate an intracellular macromolecular target [113]. To date, the major identified intracellular mechanisms include inhibition of DNA synthesis [114–117], inactivation of protein synthesis [114, 116–119], and disruption of chaperone function and protein folding [120, 121]. Furthermore, many AMPs possess chemotactic properties and aid in stimulating an immune response. For a review of the immunological role of AMPs see Oppenheim et al. [122].

## 2 NATIVE AMPHIPATHIC α-HELICAL ANTIMICROBIAL PEPTIDES

Due to the enormous diversity of AMPs in structure, size, and amino acid composition, we decided to focus this review on amphipathic α-helical AMPs. We screened the literature for all native amphipathic α-helical AMPs that met the following criteria: (1) The peptides had to show broad spectrum antimicrobial activity, at least against gram-negative and gram-positive bacteria; (2) the peptides had to have a minimum calculated hydrophobicity and amphipathicity; and (3) native peptide homologs had to have significant differences, for example, in the number of positive charges, number of negative charges, number of proline residues, or number of hydrophobic residues. With this approach, we came up with a list of 136 native peptide sequences that we subsequently evaluated. The data were tabulated for the 136 peptides as follows: name; source; length; sequence; whether the peptide had a C-terminal amide; the number of Pro residues; the number of positively charged residues; the number of negatively charged residues; the net charge on the peptide at pH 7 assuming His residues are fully deprotonated; the net charge density at pH 7, which is calculated by dividing the net charge by the number of residues in the peptide (values range from 0 to 1); the number of hydrophobic residues, which includes only the major hydrophobic residues Pro, Val, Tyr, Met, Ile, Leu, Phe, and Trp; the hydrophobic density, which is the sum of the hydrophobicity values for these eight residues in the peptide divided by the number of residues in the peptide; amphipathicity of the whole native sequence and any segment of the sequence if its amphipathicity is significantly greater than the native sequence; and, finally, hemolytic activity. The second part of the table includes the antimicrobial activity data where the minimum inhibitory concentrations (MIC values) are reported in micrograms/milliliter or micromolar for each gram-positive and gram-negative organism reported. Also included in the table is antifungal activity or other activities (e.g., activity against cancer cells). Finally, the references from where we obtained the biological data are also included. The size of this table is too large to include in this review; thus, we have made the data available on our website (sc3id.ucdenver.edu/antimicrobialpeptidereview) and refer to this table as the online table in this text. We have included a representative table (Table 1) of the most abundant group of native amphipathic AMPs, that is, 22–27 residues in length and where the native peptide had measured hemolytic activity reported along with the antimicrobial activities. Thus, Table 1 includes the information for 31 peptides.

### 2.1 General Features of Amphipathic α-Helical Antimicrobial Peptides

***Length Distribution*** As shown in Figure 3, the length distribution of native amphipathic α-helical AMPs in

**Figure 3** Length distribution of native amphipathic α-helical antimicrobial peptides included in our database. The percent of peptides of a given length containing at least one Pro is shown in open bars.

our database range from 10 to 48 residues with 85% of the peptides ranging from 16 to 39 residues in length. Only ~7% of the peptides are ≤15 residues in length and only ~7% of the peptides are ≥ 40 residues in length. Interestingly, the largest number of peptides are in the 22- to 27-residue group (34%).

***Proline-Containing Native AMPs*** Of the AMPs in our database, ~50% contain Pro residues and, as shown in Figure 3, the number of Pro residues in the peptides is length dependent. As peptide length increases, the number of peptides containing Pro increases from only 20% of peptides ≤15 residues in length to 43% of peptides in the 22- to 27-residue group to 63% in the 34- to 39-residue group to 88% in the 40- to 45-residue group. Of the peptides containing Pro, most (95%) contain 1 or 2 Pro residues (57% contain a single Pro residue and 38% contain 2 Pro residues). This is interesting, since it is well documented that Pro can disrupt the α-helical structure by putting a kink in the polypeptide chain. In fact, in a short amphipathic model α-helical peptides (18 residues) where Pro was substituted in the center of the nonpolar face, approximately 50% of the α-helical content was lost even in a hydrophobic environment (50% trifluoroethanol, a helix inducing solvent and a mimic of the hydrophobicity of the bilayer; [123]). Pro has the lowest α-helical propensity of all 20 amino acid side chains [123]. This observation fits with the fact that the occurrence of Pro in short α-helical AMPs is less than in the longer peptides (Fig. 3). In fact, all peptides in our database containing multiple Pro residues contain greater than 23 residues.

In general, all the Pro-containing AMPs are unstructured in aqueous conditions but partial α-helical structure is induced in a hydrophobic membrane-mimetic solvent like trifluoroethanol. When NMR structures have been obtained, the Pro residues are in unstructured regions. For example, fowlicidin-1 (26 residues) has a single Pro residue at position 7 and fowlicidin 3 (27 residues) has 2 Pro residues at positions 5 and 8; regions 1–7 and 1–8, respectively, are unstructured in the presence of TFE, and the remaining portions of the molecules are α-helical in 50% TFE [51]. The role Pro residues can play in amphipathic α-helical AMPs is discussed later.

***Charge*** Of the 136 AMPs in our database, we tabulated the number of peptides containing negatively and positively charged residues. As shown in Table 2, 68% of the AMPs contained negatively charged residues and 32% of the AMPs had no negatively charged residues. The number of negatively charged residues per peptide is mainly between 1 and 3 (Table 2). On the other hand, all the AMPs in our database contain positively charged residues varying between 1 and 14, with the vast majority of peptides containing between 3 and 10 positively charged residues (Table 2). Since native AMPs vary dramatically in length, probably the most important parameters with regard to charge are negative, positive, and net charge density. Charge density is defined as the number of charges or net charge in the peptide divided by the number of residues in the peptide. Thus, charge density varies between 0 and 1. However, as shown in Figure 4, the negative charge density for most AMPs is below 0.1, which implies a maximum of 1 negatively charged residue for every 10 residues in the peptide. In comparison, the positive charge density for most AMPs is between 0.1 and 0.3, that is, 1–3 positively charged residues for every 10 residues in the peptide (Fig. 4). Perhaps the most important parameter may be the net charge density, which varies between mainly +0.05 and +0.25 (Fig. 4). The domination of positively charged residues in AMPs is understandable since these peptides have to be attracted to the negatively charged surface of the prokaryotic cell membranes. The reason why so many AMPs contain negatively charged residues remains unknown. There is a relationship between the number of negative charges, the number of positive charges, and net charge with peptide length. This is shown in the

**TABLE 2 Charge Distribution in AMPs**

| Number of negative charges[a] | Number of peptides | Number of positive charges[b] | Number of peptides | Net charge[c] | Number of peptides |
|---|---|---|---|---|---|
| **0** | 44 | | | **0** | 3 |
| **1** | 44 | **1** | 4 | **+1** | 9 |
| **2** | 26 | **2** | 8 | **+2** | 18 |
| **3** | 11 | **3** | 22 | **+3** | 24 |
| **4** | 4 | **4** | 19 | **+4** | 19 |
| **5** | 5 | **5** | 16 | **+5** | 12 |
| **6** | 1 | **6** | 12 | **+6** | 18 |
| **7** | 0 | **7** | 9 | **+7** | 12 |
| **8** | 0 | **8** | 11 | **+8** | 0 |
| **9** | 1 | **9** | 12 | **+9** | 14 |
| | | **10** | 13 | **+10** | 4 |
| | | **11** | 5 | **+11** | 2 |
| | | **12** | 3 | **+12** | 0 |
| | | **13** | 1 | **+13** | 0 |
| | | **14** | 1 | **+14** | 1 |
| | **136** | | **136** | | **136** |

[a]The number of negatively charged groups in AMPs range from 0 to 9. For example, 26 AMPs have 2 negatively charged groups.
[b]The number of positively charged groups in AMPs range from 1 to 14. For example, 22 AMPs have 3 positively charged groups.
[c]The net charge in AMPs range from 0 to +14. For example, 24 AMPs have a net charge of +3.

**Figure 4** Frequency distribution of peptide negative charge densities, positive charge densities, and net charge densities included in our database. Charge density is calculated as the number of charges or overall net charge divided by the number of residues.

three-dimensional plots of Figure 5. With regard to the number of positively charged residues at a peptide length of ≤15 or 16–21 residues, the greatest number of peptides in these 2 groups contain 3–4 positively charged residues. In contrast, in the 22- to 27-residue group of AMPs, the greatest number of peptides in this group have 3–6 positively charged residues; the 28- to 33-residue group is dominated by the greatest number of peptides having 7–8 positively charged residues; and the 34- to 39-residue group is dominated by the greatest number of peptides having 9–10 positively charged residues. Thus, as the peptides become longer, there is an increase in the number of positively charged residues. In contrast, except for the peptides of ≤15 residues, the greatest number of peptides in each peptide length range (from 16 to 46 residues) contain 1–2 negatively charged residues. Note that the greatest number of peptides containing 3–4 negatively charged residues is in the 34- to 39-residue length. The comparison of net charge with peptide length is shown in the bottom panel of Figure 5. The greatest number of peptides in the 22- to 27-residue group have a net charge of +3 to +4, whereas in the 34- to 39-residue group, the greatest number of peptides have a net charge of +7 to +8. Clearly, net charge is an important parameter for AMPs over the +2 to +9 range (Table 2), where a net charge of +7 to +8 dominates the peptide length of 34–39 residues and a net charge of +3 to +4 dominates the peptide length of 22–27 residues (Fig. 5).

***Hydrophobicity*** Amphipathic α-helical AMPs must have a certain minimum hydrophobicity to penetrate the hydrophobic membrane of prokaryotic cells. Thus, the relative hydrophobicity of all 20 common amino acid side chains becomes an important parameter in understanding the mechanism of action of AMPs. We have reviewed all hydrophobicity scales reported in the literature and selected the most accurate scale for the relative differences in side-chain hydrophobicity in peptides as that reported by Kovacs et al. [124]. The side-chain hydrophobicities relative to Gly are shown in Table 3. Kovacs et al. [124] showed that the intrinsic hydrophilicity/hydrophobicity of 17 amino acid side chains (Gly, Ala, Cys, Pro, Val, nVal, Leu, nLeu, Ile, Met, Tyr, Phe, Trp, Ser, Thr, Asn, and Gln) was independent of pH and buffer conditions; in contrast, the intrinsic hydrophilicity/hydrophobicity of potentially charged side chains (Orn, Lys, His, Arg, Asp and Glu) was dependent on pH and buffer conditions, including the type of salt or ion-pairing reagent (see [124] for a detailed discussion).

In the calculation of hydrophobic density for all the AMPs, we used the sum of the hydrophobicity values in a peptide for the nonpolar residues, Pro, Val, Tyr, Met, Ile, Leu, Phe, and Trp (note that Cys does not occur in the AMPs in our database). All other side chains have considerably lower hydrophobicity values compared to these nonpolar side chains (Table 3). The sum of these values was divided by the number of residues in the AMP to give the hydrophobic densities listed in Table 1. As shown in Figure 6, the hydrophobic density varies between 6.1 and 12.0 for greater than 90% of the AMPs in our database. To put this in perspective, an AMP would require one leucine residue for every two residues to give a hydrophobic density of 12. We next compared the effect of peptide length and hydrophobic density (Fig. 7). AMPs with high hydrophobic densities of 9.1–12.0 are in the 16- to 21- and

**Figure 5** Correlation of peptide length and number of peptides in our database with the number of positive charges (top panel), number of negative charges (middle), and net charge (lower panel).

**TABLE 3 Hydrophobicity and α-Helical Propensities of Amino Acid Side Chains**

| Amino Acid Side Chain[a] | Relative Hydrophobicity at pH 7[b] | Amino Acid Side Chain | α-Helical Propensity $\Delta\Delta G$ (kcal/mol)[d] |
|---|---|---|---|
| Trp | 33.0 | Ala | –0.96 |
| Phe | 30.1 | Arg | –0.90 |
| *n*-Leu[c] | 25.9 | Leu | –0.81 |
| Leu | 24.6 | Lys | –0.70 |
| Ile | 22.8 | Met | –0.67 |
| Met | 17.3 | Gln | –0.61 |
| *n*-Val[c] | 16.9 | Ile | –0.59 |
| Tyr | 16.0 | Trp | –0.49 |
| Val | 15.0 | Phe | –0.48 |
| Pro | 10.4 | Tyr | –0.43 |
| Cys | 9.1 | Cys | –0.43 |
| His | 4.7 | Val | –0.42 |
| Ala | 4.1 | Asn | –0.33 |
| Thr | 4.1 | Ser | –0.33 |
| Arg | 4.1 | His | –0.33 |
| Gln | 1.6 | Glu | –0.32 |
| Ser | 1.2 | Thr | –0.28 |
| Asn | 1.0 | Asp | –0.21 |
| Gly | 0 | Gly | 0 |
| Glu | –0.4 | Pro | 0.83 |
| Asp | –0.8 | | |
| Lys | –2.0 | | |
| Orn[c] | –2.0 | | |

[a]Side-chain hydrophobicity was determined by reversed-phase high-performance liquid chromatography of model synthetic peptides with L-amino acid substitutions at position X in the peptide sequence Ac-X-G-A-K-G-A-G-V-G-L-amide [124].
[b]Conditions, 10 m*M* phosphate buffer, pH 7, containing 50 m*M* NaCl.
[c]*n*-Leu, *n*-Val, and Orn denote norleucine, norvaline, and ornithine, respectively.
[d]Determined in 50 m*M* phosphate buffer, pH 7, containing 0.1 *M* KCl [123].

22- to 27-residue length groups. The 22 to 27-residue length has the greatest number of peptides with this high hydrophobic density. When the AMPs get longer (34–39 residues), the vast majority of the peptides of this length have lower hydrophobic densities (6.1–9.0). There are much fewer peptides of this length with a hydrophobic density greater than 9.0 or less than 6.1 (Fig. 7).

***Amphipathicity*** Amphipathic α-helical AMPs have a nonpolar face with a concentration of nonpolar amino acid residues and a polar face with a concentration of polar and charged amino acid residues. Amphipathicity of the AMPs included in this review was determined by the calculation of hydrophobic moment [125] using the software package Jemboss version 1.2.1 [126] modified to include the hydrophobicity scale shown in Table 3 [124].

As shown in Figure 8, the majority of native amphipathic α-helical AMPs have amphipathicity values ≥3.0 (~70%) and the number of AMPs with amphipathicity values between 3 and 6 is ~56%. The AMPs with the highest amphipathicity values (>6.0) were the 16- to 21-residue group. The greatest number of AMPs with amphipathicity values between 3 and 6 were the 22- to 27-residue group, and the greatest number of AMPs with amphipathicity values between 1.0 and <3 were the 34- to 39-residue group (Fig. 8). Thus, there is a general trend of decreasing peptide amphipathicity with increasing peptide length.

An example linking calculated amphipathicity with peptide sequence is shown in Figure 9. Thus, the sequence of K13, a 26-residue AMP, is shown in Figure 9 (left) presented as a helical wheel diagram. Even with a lysine residue in the center of the nonpolar face, the peptide has a high amphipathicity value of 4.92. To place this value in perspective, the sequence can be shuffled at all positions other than lysine 13 to give a minimum amphipathic value of 0.14 for a nonamphipathic sequence (Fig. 9, middle) up to a maximum value of 6.74 when residues are shuffled to optimize amphipathicity (Fig. 9, right).

***Peptide Self-Association*** Peptide self-association is an extremely important parameter in understanding the mechanism of action of amphipathic α-helical AMPs. These peptides have a very hydrophobic nonpolar face that promotes dimerization/oligomerization in aqueous solution. Since no method existed to measure peptide self-association of small amphipathic molecules with the sensitivity to measure, for example, the effect of a single substitution on the nonpolar face of these molecules, we developed a novel technique referred to as "temperature profiling in reversed-phase high-performance liquid chromatography (RP-HPLC)," based on the observation of the conformation-dependent response of peptides to temperature variations during RP-HPLC.

We have applied this technique to several types of peptides, including amphipathic cyclic β-sheet AMPs [127], monomeric α-helices and α-helices that dimerize [128], as well as α-helices that dimerize to form α-helical coiled coils [129]. Although peptides are eluted from a reversed-phase column mainly by an adsorption/desorption mechanism, even a peptide strongly bound to a hydrophobic stationary phase will partition between the matrix and the mobile phase when the acetonitrile content becomes high enough during gradient elution. The proposed mechanism of action for temperature profiling of α-helical peptides in RP-HPLC has been explained in detail by Mant et al. [128]. In summary, the

**Figure 6** Distribution of hydrophobic densities of peptides in our database. Hydrophobic density is calculated using the relative amino acid hydrophobicity scale [124] in Table 3. The hydrophobicity values for the nonpolar residues Pro, Val, Tyr, Met, Ile, Leu, Phe, and Trp is summed and the total is divided by the number of residues in the peptide to produce the density value.

**Figure 7** Correlation of peptide length and number of peptides in our database with calculated hydrophobic density.

mechanism is based on four assumptions: (i) at low temperature, just as an amphipathic α-helical peptide is able to self-associate in aqueous solution (through its hydrophobic, nonpolar face), it will dimerize/oligomerize in solution during partitioning in RP-HPLC; (ii) at higher temperatures, the monomer–dimer equilibrium favors the monomer as the dimer is disrupted; (iii) at sufficiently high temperatures, only the monomer is present in solution; and (iv) the amphipathic α-helical peptide is always bound in its monomeric helical form by its preferred binding domain (the nonpolar face) to the hydrophobic stationary phase, that is, the peptide dimer can only be present in solution, and disruption of the dimer is required for rebinding to the reversed-phase matrix during partitioning.

Figure 10 shows the temperature profiles of the AMP, K13, shown in Figure 9, along with the peptide where position 13 is valine rather than lysine during RP-HPLC from 5 to 80°C. The maximal value of the change of peptide retention times with temperature

normalized to 5°C (Fig. 10A) and subsequently normalized to that of a control peptide with negligible secondary structure (Fig. 10B) is defined as the peptide association parameter ($P_A$) to quantify the association ability of peptide analogs in solution. Figure 10 shows that the substitution of Val by Lys dramatically reduces the ability of the peptide to self-associate. For details of this method and its value in monitoring self-association of amphipathic α-helical AMPs, see [130–133]. The $P_A$ values of peptides with nonpolar face substitutions were of the same order as their relative hydrophobicity, indicating that the hydrophobicity on the hydrophobic face of the amphipathic helix was essential for dimerization, since the dimers are formed by the binding together of the nonpolar faces of two amphipathic molecules. In general, the greater the hydrophobicity on the nonpolar face the greater the amphipathicity and the greater the association of peptides by their nonpolar faces. The importance of peptide self-association in the mechanism of action of AMPs is discussed below.

**Figure 8** Correlation of peptide length and number of peptides in our database with calculated peptide amphipathicity. Amphipathicity is derived by calculating the hydrophobic moment [125] using the Jemboss [126] software package and the hydrophobicity scale [124] shown in Table 3.

## 2.2 Biological Activity

Among our 136 representative α-helical AMPs, 53 are from amphibians, 31 are from insects, 20 are from mammals, 10 are from fish, 7 are from spiders, 6 are from scorpions, 3 are from birds, and 6 are from other organisms. All of them exhibit high levels of antibiotic activity.

***Antibacterial Activity*** Most studies on AMPs to date have been carried out on those with antibacterial activity [134], with no obvious conserved structural domains giving rise to antibacterial activity [4]. The antibacterial activities of AMPs are in the micrograms/milliliter or micromolar level. Among the 136 representative α-helical AMPs, 130 have anti-gram-negative bacterial

**Figure 9** Helical wheel [327] representation of the 26 residue K13 peptide. The nonpolar face is indicated by the open arc and the polar face is represented by the closed arc. Residues contributing to the polar face are circled white for Ser, Thr, and His residues. Positively charged residues are shaded dark gray and hydrophobic residues are shaded light gray. Amphipathicity values are in parentheses. (Left) Highly amphipathic native K13 peptide. (Middle) A nonamphipathic peptide constructed by shuffling the sequence at all positions except K13. (Right) K13 peptide optimized for high amphipathicity by shuffling residue positions.

**Figure 10** Measurement of K13 and V13 peptide self-assembly using RP-HPLC temperature profiling. (A) The retention time for each peptide at a given temperature is normalized to the retention time at 5°C using the expression ($t_R^t$-$t_R^5$), where $t_R^t$ is the retention time at a given temperature and $t_R^5$ is the retention time at 5°C. (B) The retention properties of each peptide were further normalized against a control peptide with minimal secondary structure using the expression ($t_R^t$-$t_R^5$ for K13) - ($t_R^t$-$t_R^5$ for control peptide). The maximal change in retention relative to the control peptide is defined as the peptide association parameter ($P_A$).

activity reported, while 135 have anti-gram-positive bacterial activity reported (online table). *E. coli* and *Pseudomonas aeruginosa* are the commonly used gram-negative bacteria for activity assays. Among those anti-gram-negative-bacterial peptides, 119 have been proved to be efficient against *E. coli*, while 81 have activity toward *P. aeruginosa* (online table), some of which act even against clinical isolates of *Pseudomonas* [135, 136]. Citropin 1.1 [135], IsCT [137], and melittin B [138] have effects on antibiotic-resistant *P. aeruginosa* strains. Some special microorganisms were used to evaluate the activity of certain AMPs from rare sources. For example, *Vibrio anguillarum* and *Vibrio vulnificus*, gram-negative fish pathogens, were treated with chrysophsins, a peptide family from red sea bream—*Pagrus major* [139]. One hundred and ten α-helical AMPs have antibacterial activity against *Staphylococcus aureus*, the gram-positive bacterium frequently used for activity assays. Methicillin-resistant *S. aureus* (MRSA), a resistant variation discovered in 1961 [140], has evolved an ability to survive treatment with many antibiotics including gentamicin, tobramycin, netilmicin, and amikacin [141]. MRSA is especially troublesome in hospital-acquired (nosocomial) infections. Twenty-three α-helical AMPs were shown to kill MRSA effectively. Almost half of them (10 of 23) are mammalian cathelicidins (an AMP family, which share a well-conserved N-terminal segment, the cathelin domain, that is proteolytically cleaved to generate the mature, active peptide contained within the C terminus [4]) (online table). Vancomycin-resistant *Enterococcus* (VRE) is a group of bacterial species of the genus *Enterococcus* that is resistant to the glycopeptide antibiotic vancomycin. VRE was discovered in 1985 [142] and is particularly dangerous to immunocompromised individuals. VRE is also troublesome in hospital-acquired infections. Eight of 136 representative AMPs can inhibit VRE in vitro and half of them (4 of 8) are from amphibians (which have proved to be a rich source of AMPs [4]) (online table).

***Antifungal Activity*** Peptides with mainly antifungal activity (e.g., many isolated from plants) are generally rich in polar and neutral amino acids, which suggests a unique structure–activity relationship [143]. Interestingly, in a similar manner to antibacterial AMPs, no obvious conserved structural domains that give rise to antifungal activity are present [4]. Indeed, the mechanism of action of some antifungal peptides is still not clear [4]. Among 69 representative α-helical AMPs with antifungal activity, 57 of them have candidacidal activity (online table). *Candida albicans*, a diploid fungus, is a causal agent of opportunistic oral and genital infections in humans [144]. Systemic fungal infections (fungemias) have emerged as important causes of morbidity and mortality in immunocompromised patients, including AIDS (acquired immunodeficient syndrome) [145, 146]. In addition, hospital-related infections in patients have become a cause of major health concern. Seven peptides can kill the clinical isolates of *C. albicans* and 4 of them are cathelicidins (online table). For example, pleurocidin, a 25-residue α-helical AMP from the winter flounder *Pleuronectes americanus* can kill four *C. albicans* clinical isolates with MIC (minimum inhibition concentration) values ranging from 15.4 to 24.8 μg/mL [147].

Fifteen α-helical AMPs (7 from amphibians) kill some *Aspergillus* species in vitro (online table), which cause serious disease in humans and animals. The most common causes of invasive disease are *A. fumigatus* [148] and *A. flavus* [149]. Eleven and 9 α-helical AMPs can kill these species, respectively (online table). Life-threatening infections caused by the encapsulated fungal pathogen *Cryptococcus neoformans* have been increasing steadily because of the onset of AIDS and the expanded use of immunosuppressive drugs [150]. Twenty-four *C. neoformans*–killing AMPs have been reported (online table). PMAP-36 (pig myeloid antibacterial peptide-36) [151] and SMAP-29 (sheep myeloid antibacterial peptide-29) [152], cathelicidins from pig and sheep, respectively, have activity against clinical isolates of *C. neoformans.*

***Antiviral Activity*** AMP antiviral activity frequently appears to be related to the viral adsorption and entry process [153] or results from a direct effect on the viral envelope [154, 155]. Despite diverse AMP structures, many of these peptides exhibit similar antiviral modes of action [156, 157], indicating that, despite large structural differences, these peptides are able to interact with their targets perhaps due to the fact that AMPs are known to adopt amphipathic conformations intrinsic to antibacterial and antiviral activity [4]. Interestingly, although the viral target of these peptides appears to vary, the demonstrated antiviral effects are quite similar. Sixteen α-helical AMPs (10 from amphibians) displayed antiviral activity to different human viruses, including human immunodeficiency virus (HIV) and herpes simplex virus (HSV) (online table).

***Antiprotozoan Activity*** Magainin 2 was one of the first AMPs demonstrated to display antiprotozoan activity [158]. Although several AMPs possess antiprotozoan activity, structure–activity relationship studies suggest that antiprotozoan and antiviral activities are mediated by different mechanisms [159]. Indeed, it is likely that antiprotozoan activity is due to the presence of peptide motifs fundamentally different from those typical of activity against bacteria, virus, and fungi. Twelve native α-helical AMPs (7 from amphibians) showed antiprotozoa activity besides magainin 2 (online table). *Leishmania* is a genus of trypanosome protozoa and is the parasite responsible for the disease leishmaniasis (kala azar, black fever) [160]. Four of 136 α-helical AMPs exhibit inhibition activity against *Leishmania* (online table).

***Antitumor Activity*** Tumor cells and nontransformed cells may differ in membrane composition. For example, there is a 3- to 7-fold higher phosphatidylserine content in melanoma and carcinoma cell membranes compared to normal human keratinocytes [161]. Such differences in membrane composition can result in higher susceptibility of tumor cells to membrane-permeabilizing peptides [162]. Thirteen α-helical AMPs with antitumor activity have been reported, 10 of them from amphibians. The tumor cells tested are derived from a variety of different organs. For example, aurein 1.2, a 13-residue α-helical AMP from the Australian frog *Litoria aureus* was active against lung, colon, prostate, and breast cancer cells with $LC_{50}$ (minimum concentrations required to kill 50% of the cancer cells) values around 0.01 μ*M* [163].

***Other Antibiotic Activity*** Among the nine insecticidal AMPs, four of them are from spiders and four of them are from insects (online table). Besides insecticidal activity, AMPs also present additional properties [162], such as mitogenic activity [164], participation in signal transduction pathways [165], and adaptive immune responses [166].

***Hemolytic Activity*** Erythrocyte hemolysis is a commonly used in vitro assessment of AMP toxicity. The basic assay consists of exposing red blood cells (RBCs) to AMP-containing solutions for a given period of time, centrifugation to separate lysed cells, and ultraviolet (UV) measurement of hemoglobin released into the supernatant. Many variations of the assay exist, and inconsistencies in RBC source, peptide exposure time, and reporting of peptide concentrations impede comparison of AMP toxicity across structural classes and research groups. Each parameter is discussed below and recommendations are suggested for a common hemolysis assay.

*Red Blood Cell Source* A number of RBC sources including human [132], canine [167], sheep [76], and rabbit [168] have been used to assess hemolysis. Any source is acceptable for obtaining a hemolysis profile of a series of peptide analogs. However, nonhuman RBC results should not be compared to human RBC hemolysis data. Membrane lipid composition varies among mammalian species, and vastly different hemolysis results have been obtained across species [167, 169, 170]. Crowell demonstrated that the sphingomyelin content of canine, human, and sheep erythrocyte membranes (12.4, 25.0, and 53.1%, respectively) was inversely correlated with RBC vulnerability to a pore-forming peptide derived from *P. aeruginosa*, and the $EC_{50}$ (effective concentration of cytotoxin required for 50% loss of the intracellular cation) using human RBCs was approximately 52-fold that of canine RBCs and less than 25% that of sheep RBCs [170]. Similarly, analysis of the

hemolytic ability of SMAP-29 at 80 μ*M* showed only 3% lysis of sheep RBCs versus 67% lysis for human [169]. Given such drastically different results using erythrocytes from different species and the desire to develop AMPs for human clinical use, we recommend using human RBC for hemolysis assays.

*AMP Exposure Time* The length of time erythrocytes are exposed to AMPs during the hemolysis assay is the least standardized parameter of the method. Reported protocols have exposures ranging from 10 min [171] to 24 h [171, 172]. The most commonly cited times are 30 min [42, 173, 174] and 1 h [11, 175, 176]. Such short exposures provide valuable information about relative acute toxicity across a peptide series. However, higher exposure times are necessary to evaluate the longer term toxicity that could result if AMPs are not fully metabolized and cleared within 1 h in vivo. For example, time-course studies using the D-V13$A_L$ peptide showed substantially greater hemolysis when the exposure is increased from 1 to 8 h (Fig. 11, [131]), and similar examination of the L-V13$A_D$ peptide showed a dramatic shift in minimal hemolytic concentration from 250 μg/mL at 12 h [130] to 31.3 μg/mL at 18 h [131]. Therefore, we suggest hemolysis should be measured using a time-course approach extending to at least 8 h of exposure time (Fig. 11).

*Peptide Concentration* AMP concentration is routinely reported in either micromolar or micrograms/milliliter. The majority of published studies investigate and report the hemolytic ability of a series of peptide analogs containing the same number of residues and very similar molecular masses. Under such circumstances, the unit of concentration has negligible effects on data interpretation. However, a comparison of hemolytic ability of two AMPs with significantly different molecular masses should use a unit of molarity to avoid a mass bias. Consider the example of the hemolysis induced by bPaAP and bPcAP peptides (bullfrog pepsinogen A or C-derived peptide). The peptide solutions used in a hemolysis assay were reported using microgram/milliliter concentrations despite the fact that the molecular masses are approximately 1865 and 3692, respectively [177]. The mass difference produced nearly a twofold greater number of bPaAP molecules used at each assay point compared to the number of bPcAP molecules. Such a significant difference would have confounded interpretation if differential hemolysis had been observed. Therefore, we advocate the reporting of hemolysis data using a unit of molarity to describe AMP concentration.

***Cytotoxicity*** Although erythrocyte hemolysis is a useful method for initially evaluating AMP toxicity and screening peptide analogs, more extensive cytotoxicity testing using additional cell types should be performed to improve biological significance. The anticipated therapeutic site dictates the cell type most appropriate for use in cytotoxicity assays. For example, AMPs designed to treat bacterial infections in the lungs of cystic fibrosis patients should be tested using lung epithelial cells.

**Figure 11** Time-course study of the effect of AMP exposure time on hemolysis. Different peptide concentrations are shown using different symbols. Open symbols represent D-peptides, and closed symbols represent L-peptides.

AMPs with intended systemic circulation and parenteral administration should be tested additionally for endothelial and lymphocyte toxicity. Similar to hemolysis, no common assay conditions exist. The most popular assays for cell viability are based on metabolic activation of a dye or reduction of a tetrazolium salt by viable cells and subsequent fluorescent or UV spectrophotometric measurement. Common examples include alamarBlue (Invitrogen, USA) [51, 58], MTT (Invitrogen, USA) [168, 178, 179], and WST-1 (Roche Applied Science, USA) [180]. In an alternative method, lactate dehydrogenase (LDH) released into the media by lysed cells is used to reduce a tetrazolium salt reagent and to produce a colorimetric response proportional to the number of lysed cells. The LDH method, sold as CytoTox96 by Promega Corporation, USA, successfully measured the cytotoxicity of pseudin-2 in mouse fibroblast cells [181]. Targeted dyes such as trypan and propidium iodide (PI) [182] provide information about cell membrane condition without metabolic activation. Live cells with intact membranes exclude trypan or PI and remain unstained, unlike dead cells with compromised membranes. Trypan exclusion [172, 183] and PI staining [184] have been successfully used for AMP cytotoxicity assessment. The comparability of these assay methods has been questioned [185, 186]. Assays that require cell mixing or transfer show significantly higher cell death compared to assays that measure viability in the original seeding well [185]. Therefore, we recommend that all assays attempt to eliminate or limit cell transfer from the original growth plate. Regardless of the assay chosen, the time cells are exposed to AMPs must be considered. Reported AMP exposure time ranges from 15 min [187] to 4 days [188]. In order to calculate a relevant therapeutic index, the cytotoxicity exposure time should reflect the time scale used to assess antimicrobial activity. As many antimicrobial assays use 18–24 h [130, 189, 190], we suggest 18–24 h for cytotoxicity assessment.

***Resistance to AMPs*** Pathologically relevant bacteria constantly encounter host defense systems, including AMPs found within neutrophil granules. Not surprisingly, a wide range of microorganisms including *P. aeruginosa*, *S. aureus*, and *Neisseria gonorrhea* have developed resistance mechanisms against host AMPs and analogs. To date, characterized resistance systems include modifications to lipopolysaccharide (LPS), non-LPS membrane alterations, efflux pumps, and protease-mediated degradation.

*Alterations in LPS* LPS is the outermost component of gram-negative bacteria and the first structure encountered by an AMP. Composed of an outer O-specific side-chain oligosaccharide, a polysaccharide core, and an inner lipid A (endotoxin) particle, LPS possesses a negative charge conducive to electrostatic interactions with cationic AMPs. Reduction of the LPS negative charge offers one common mechanism of AMP resistance found in several species. *Salmonella typhimurium* and *P. aeruginosa* use the PhoP/PhoQ genetic regulatory system to induce changes in LPS charge and defend against AMPs. PhoP/PhoQ activates the PmrA–PmrB system and results in the addition of aminoarabinose to lipid A [191–194]. The subsequent charge reduction has been shown to confer resistance to polymyxin [191, 193, 194] and magainin [195]. A similar pattern of aminoaribinose addition to lipid A has been observed in *Proteus mirabilis* and induces resistance to polymyxin and protegrin [196]. Additionally, PhoP/PhoQ can activate pagP and subsequently acylate lipid A, thereby neutralizing the surface charge and providing resistance to the α-helical antimicrobial C18G peptide [197]. Other significant LPS modifications that create AMP resistance include the loss of the O-specific side chains in *Bodetella bronchioseptica* [198] and the inclusion of phosphorylcholine as a LPS component in *Haemophilus influenzae* [199].

*Other Membrane and Capsular Modifications* Several other membrane modifications have been reported to provide AMP resistance. Teichoic acids are negatively charged components of gram-positive cell walls that create favorable electrostatic potentials for cationic AMP binding. Peschel has shown that wild-type *S. aureus* can reduce the negative charge of teichoic acids by conjugation with D-alanine using a *dlt* operon-mediated process [200]. Confirming the role of the D-Ala modification in resistance, *dlt* deletion mutants showed marked magainin susceptibility in contrast to wild-type strains [200]. *S. aureus* also reduces the negative membrane charge by addition of the positively charged amino acid L-lysine to phosphotidylglycerol, and mutants incapable of lysine addition show increased susceptibility to defensins, magainin II, and HNP-1 [201, 202]. Another AMP defense is invoked by *Klebsiella pneumonia.* In response to polymyxin, *Klebsiella* increases the capsule polysaccharide thickness, limits the antimicrobial agent's access to the cell membrane, and decreases susceptibility [203].

*Efflux Pumps* Bacterial efflux pumps can move damaging antibiotics, dyes, and detergents across the cell membrane, and in cases of gram-negative bacteria these agents are also transported across the outer membrane. See Nikaido for a detailed mechanistic review [204]. *Yersinia enterocolitica* actively removes polymyxin using the RosA/RosB efflux pump [205]. Similarly, *N. gonorrhea*'s resistance to the human α-helical AMP, LL-37,

has been demonstrated to be dependent on the *mtr* efflux pump [206].

*Protease-Mediated Degradation* Extracellular proteases capable of cleaving and inactivating AMPs have been reported in several bacterial species. *E. coli* and *P. mirabilis* express the ZapA metalloprotease that has been shown to degrade LL-37 and diminish antimicrobial activity [207]. The metalloprotease autolysin has also been found to inactivate LL-37 and confers resistance in *S. aureus* [208]. In addition to the LPS modifications mentioned previously, induction of the PhoP/PhoQ regulatory system increases PgtE protease activity in the outer membrane of *S. typhimurium* and renders the bacteria resistant to LL-37 and C18G [209].

*Overview of Resistance to AMPs* Despite these means of generating AMP resistance, the practical clinical relevance remains unclear. Repetitive passaging of 27 clinical isolates of *S. aureus* in the presence of pexiganin, a magainin analog, at subinhibitory concentrations showed less than a twofold increase in MIC, whereas similar exposure to the small-molecule antibiotic mupirocin produced an eightfold reduction in susceptibility [6]. Similarly, Steinberg reported difficulty producing methicillin-resistant *S. aureus* (MRSA) or *P. aeruginosa* strains resistant to protegrin-1 using more than 10 passages at 50% MIC [5]. *These results suggest that although resistance is possible, it is by no means widespread or easily developed, and AMPs remain viable candidates for therapeutic development.*

## 3 MECHANISM OF ACTION

### 3.1 Cell Membrane

In order to understand the mechanism of action of AMPs, a thorough knowledge of the structure of the major target cell membrane is necessary. Thus, bacterial membranes are negatively charged with lipids bearing phospholipid headgroups: phosphatidylglycerol (PG), cardiolipin (CL), or phosphatidylserine (PS). In contrast, mammalian membranes are enriched in zwitterionic phospholipids (neutral in net charge): phosphatidylethanolamine (PE), phosphatidylcholine (PC), or sphingomyelin (SM) [210, 211]. Most of such anionic lipids of mammalian membranes are sequestered on the cytoplasmic side of the membrane while being exposed to the external medium with microbial membranes [17]. In addition, according to Matsuzaki, the presence of cholesterol, a major constituent of mammalian cellular membranes, can reduce the activity of AMPs by stabilizing the lipid bilayer or directly interacting and neutralizing them [212].

### 3.2 Models of Membrane Disruption

As previously described, the main target of AMPs is the cytoplasmic membrane. However, their interaction is nonspecific, an observation supported by the following evidence: (1) AMPs have broad-spectrum activity; (2) their speed of action is often within minutes in vitro; (3) both D- and L-peptide enantiomers of many AMPs have activity that indicates that there is no stereoselective interaction with a chiral enzyme, lipid, or protein receptor [213]. Generally, AMP action is almost universally dependent upon interaction with and permeabilization of the target cell membrane, with peptide net positive charge, hydrophobicity, and flexibility having been discovered as the driving physical forces [4, 214–216]. Regardless of the time required, or the specific antimicrobial mechanism, four specific and consecutive steps must occur in order to induce bacterial killing: attraction, attachment or self-promoted uptake, permeabilization, and membrane leakage.

***Attraction*** Attraction is considered to be the electrostatic interactions between peptides' cationic residues and negatively charged groups in the outer bacterial envelope. These interactions are effective over relatively long distances. Lipoteichoic acids, teichuronic acid, and amino acid carboxyl groups in the multilayered peptidoglycan [217] are the main source of negative charges of gram-positive bacterial membranes [4]. For gram-negative bacterial membranes, negative charges arise from phosphate groups within the LPS [4]. As noted previously, LPS can be subdivided into three specific regions: the O-antigen, the core, and lipid A. Lipid A molecules are negatively charged, and the outer membrane leaflet structure is held together in part by the binding of divalent cations. LPS, in particular lipid A, plays an important role in the pathophysiology of gram-negative bacterial sepsis [17].

***Attachment or Self-Promoted Uptake*** Once close to the microbial surface, AMPs must traverse capsular polysaccharides (LPS or outer membrane) before they can interact with the cytoplasmic membrane of gram-negative bacteria; on the other hand, AMPs have to traverse capsular polysaccharides, teichoic acids, and lipoteichoic acids in order to interact with the membrane of gram-positive bacteria [218]. On the surface of gram-negative bacteria, AMPs first remove or displace $Ca^{2+}$ or $Mg^{2+}$, which destabilizes the outer membrane [4]. AMPs then disrupt noncovalent bridging interactions between LPS molecules in a process driven by hydrophobic interactions, thus altering the ordered supramolecular arrangement of this leaflet, and leading to a disturbance of the outer membrane structure [4]. This

action possibly involves folding of the AMPs into a membrane-associated structure, which is different than the aqueous structure [213]. Many linear AMPs only adopt amphipathic structures when they are in contact with membranes, membrane-mimicking environments [25, 171], or when they are aggregated [219]. This transition of linear to structured peptide produces about 50% of the energy needed for membrane association [213, 220].

***Permeabilization*** For most AMPs, permeabilization of microbial membranes is an early and necessary step for killing microbes [221–223]. The molecular mechanism of membrane perturbation and disruption clearly depends on a number of parameters, for example, the nature of the peptides, temperature, environmental conditions, and peptide-to-lipid ratio [221]. In Huang's two-state model [213], he called the state observed at low peptide (P)/lipid (L) ratio the S state (functionally inactive, peptide embedded into the lipid head group), and the state observed at P/L ratio above the threshold P/L* the I state (functionally active, peptide inserted into the bilayer), for both α-helical and β-sheet peptides. He proposed that the action of AMPs is effected by the transition from the S state to the I state. Given the same peptide concentration, cells with a low P/L* threshold will be lysed while the cells with a high P/L* threshold may survive. Self-assembly of peptides was also observed for natural and synthetic AMPs [224–226].

To date, there are four major models (barrel-stave model, toroidal-pore model, carpet model, and aggregate Model; Table 4, Fig. 12) to explain the mechanism of permeabilization. All of them have two common features: (1) amphipathicity as a key characteristic and (2) parallel orientation on the surface of the membrane as a first step [4].

**TABLE 4 Summary of Permeabilization Models**

| Model Name | Orientation to the Membrane | Pore Size | Example |
|---|---|---|---|
| Aggregate model | No particular orientation | — | Polyphemusin |
| Toroidal-pore model (wormhole) | Perpendicular | Varies | Magainins, melittin, LL-37, protegrin-1, MSI-78 |
| Barrel-stave model (helical-bundle) | Perpendicular | Consistent | Alamethicin, gramicidin S |
| Carpet model | Parallel | Varies | Ovispirin, dermaseptin S, cecropin, melittin, caerin 1.1 |

**Figure 12** Models of membrane disruption by antimicrobial peptides. (Adapted from Brogden [218].)

*Barrel-Stave or Helical-Bundle Model* This model was originally based on alamethicin, a 20-residue α-helical antimicrobial peptaibol from the fungus *Trichoderma viride* [227, 228]. In this model, peptides insert in a perpendicular orientation to the plane of the bilayer, forming the "staves" in a "barrel"-shaped cluster, with the hydrophilic regions of the peptides facing the lumen of the pore (point inward producing an aqueous pore) and the hydrophobic regions interacting with the lipid bilayer [4, 210, 218]. A disadvantage of this model is that it cannot explain the variety of pore sizes observed [4], although this model does appear to apply to cytotoxic peptides (toxins) such as pardaxin [217]. However, a recent hypothesis provides an explanation for this problem. When bound peptide reaches a threshold concentration, peptide monomers self-aggregate and insert deeper into the hydrophobic membrane core. The pore is a dynamic structure, and, hence, the continued recruitment or loss of peptide monomers results in a relatively polydisperse pore size [210]. α-Helical peptides require a minimal length of about 22 amino acids in order to traverse the lipid bilayers; alternatively, 8 amino acids are required if the peptide adopts a β-sheet structure [229]. Although proposed more than a decade ago, experimental evidence still supports this mechanism of membrane permeabilization for gramicidin S, a 10-residue cyclodecapeptide from gram-positive bacterium *B. brevis* [230].

*Toroidal-Pore or Wormhole Model* This model was first suggested by Matsuzaki and colleagues based on the well-known AMP magainin 2, a 23-residue α-helical peptide from the frog *X. laevis* [28, 29]. In this model, AMPs insert in a perpendicular orientation to the plane of the bilayer, with the hydrophilic regions of the peptides associating with the phospholipid head groups and the hydrophobic regions associating with the lipid core [4]. In this process, peptide and lipid together form well-defined pores and the membrane also curves inward to form a hole [210]. The lipids in these holes tilt from the lamellar normal and connect the two leaflets of the membrane, thus forming a continuous bend from top to bottom in the fashion of a toroidal hole. The pore is lined by both the peptides and the lipid head groups, which are likely to screen and mask cationic peptide charges [218]. Water-filled cavities, resembling "wormholes," are present [221]. It should be noted that the toroidal model differs from the barrel-stave model in that the peptides are always associated with the lipid head groups even when they are perpendicularly inserted into the lipid bilayer [218]. Other examples for this model are melittin, a 26-residue α-helical AMP from the honeybee *A. mellifera* [231], and LL-37, a 37-residue α-helical AMP from humans [232].

*Carpet Model* This model was proposed for the first time to describe the mode of action of dermaseptin I, a 34-residue α-helical AMP from the frog *Phyllomedusa sauvageii* [233]. In this model, AMPs aggregate parallel to the lipid bilayer, coating local areas in a "carpet"-like fashion. It is thought that this results in a detergent-like activity at a given threshold concentration, with subsequent formation of micelles and membrane pores [4]. Stepwise mechanisms involved in this model are: (1) preferential binding of the peptide monomers to the phospholipid head groups [234]; (2) alignment of peptide monomers on the surface of the membrane such that their hydrophobic faces are embedded relatively shallowly within the hydrophobic region of the membrane, and their positive charges are directed toward the hydrophilic region [233]; and (3) disintegration of the membrane by the peptide through disruption of the bilayer curvature [234]. The presence of negatively charged lipids helps in the formation of a dense peptide carpet, as they help to reduce the repulsive electrostatic forces between positively charged peptides [221]. There is more in vitro evidence for the carpet model than in vivo observations. Despite differences in secondary structure, the overall shape of each AMP is roughly cylindrical with hydrophobic side chains on one side of the cylindrical axis and hydrophilic side chains on the other. The minimum free energy configuration is for a single peptide adsorbing on the bilayer's hydrophilic–hydrophobic interface with the cylindrical axis more or less parallel to the plane of the bilayer [213]. Equilibrium between monomeric peptides and peptide aggregates that result in concentration-dependent effects also must be taken into account [221, 235]. This mechanism has also been proposed for ovispirin, a rationally designed α-helical AMP based on the sheep cathelicidin SMAP-29 [236].

*Aggregate Model* This model, which has some similarity to the toroidal-pore model, was first developed by Wu and colleagues based on the study of all four structural classes of AMPs [237]. In this model, AMPs reorient to span the membrane as an aggregate with micellelike complexes of peptides and lipids, but without adopting any particular orientation [4]. The advantage of this model is that it can explain both membrane permeabilization (generating channels with a variety of sizes and forms) and translocation across the bilayer. These are known to occur for several peptides [4], such as polyphemusin, an 18-residue β-hairpin AMP from the horseshoe crab *Limulus polyphemus* [238].

***Membrane Leakage*** Membrane leakage may involve: (1) membrane depolarization [217]; (2) leakage of essential metabolites [217]; (3) loss of compositional

specificity in the membrane due to an increased rate of phospholipid flip-flopping [29] and, for gram-negative bacteria, exchange with the inner leaflet of the outer membrane [239]; (4) translocation of the peptides to the cytoplasmic side of the membrane [29, 240], where they can interfere with important cellular mechanisms and/or trigger enzymes that cause peptidoglycan autolysis [241]; and (5) a passage of ions lowering the proton gradient and destroying the membrane potential, thus stopping adenosine triphosphate (ATP) production and all cellular metabolism and, hence, causing cell death [213]. The formation of pores affects cellular respiration, deprives sensitive organisms of their source of energy by disrupting the electrochemical gradient across free-energy transducing membranes, and results in increased water and ion flow across the membrane, concomitant with cell swelling and osmolysis [221]. Characteristics that may determine the rate of leakage are membrane charge, membrane curvature, and other factors [17].

***Methodology*** A variety of methods [218] have been employed to study the mechanism of action of AMPs including: (1) microscopy (confocal laser-scanning microscopy [242], scanning and transmission electron microscopy [243], and immunoelectron microscopy [244]); (2) studies with model membranes (X-ray crystallography [245], NMR spectroscopy [26, 246], FTIR spectroscopy [247, 248], Raman [249], and fluorescence [250]); (3) fluorescent dyes (measured by the release of internal fluorescent-labeled dextran, immunoglobulins, calcein, or other probes [251–255]); (4) ion channel formation (the ability of AMPs to attach to and penetrate the bilayer is measured by the conductivity of an electrical current generated through the subsequently formed pore [256–258]); (5) circular dichroism and orientated circular dichroism [130, 137, 259]; (6) solid-state NMR spectroscopy [260, 261]; (7) neutron diffraction [262–265]; (8) lamellar X-ray diffraction [137, 266]; (9) synchrotron-based X-ray scattering [267]; (10) isothermal titration calorimetry [268, 269] and (11) differential scanning calorimetry [270].

## 4 STRUCTURE-ACTIVITY RELATIONSHIPS IN AMPHIPATHIC α-HELICAL ANTIMICROBIAL PEPTIDES

### 4.1 Hybrid Amphipathic α-Helical Antimicrobial Peptides

Cecropin A, a 37-residue peptide from moths, was the first insect antibacterial peptide to be reported [66]. Other peptides with potent antimicrobial activity are the 26-residue melittin B from the honeybee *A. mellifera* and the 23-residue magainin-2 from the frog *X. laevis*. To develop a wider spectrum of activity and improve potency without undesirable cytotoxic effects, researchers began a program of designing hybrid peptides of cecropin A and either magainin-2 or melittin B [271–279]. Representative examples of hybrid peptides are shown in Table 5. Interestingly, melittin B was extremely hemolytic (100% hemolysis at 1 μg/mL), whereas the hybrid peptide consisting of the N-terminal basic region of cecropin A followed by the hydrophobic N terminal of melittin B referred to as cecropin A (1–8) melittin B (1–18) showed no hemolysis (Table 5). Shorter hybrids, for example, cecropin A (1–8) melittin B (1–12) still retained hemolytic activity on human red blood cells under physiological conditions [274] (Table 5). However, substitution of Thr 18 and Thr 19 with lysine residues caused a dramatic reduction in hemolytic activity while providing a twofold higher antifungal activity ([274], Table 5). Figure 13 shows a helical wheel presentation of the hybrid peptides as one continuous helix and as two α-helical segments because of the hinge region in the GIG segment between cecropin A 1–8 and melittin 1–18, melittin 1–12, or magainin-2 (1–12) (to be discussed below). The amphipathicity is substantially higher when considered as two segments for these hybrid peptides. For example, the amphipathicity of cecropin A (1–8) melittin (1–12) is 2.07 when calculated as one continuous α-helix, whereas the amphipathicity for each segment is 6.51 and 5.59 for residues 1–9 and residues 10–20, respectively. The values in brackets in Table 5 denote the calculated average of the amphipathicities for the two segments (N-terminal helical segment and the C-terminal helical segment). These results suggest that the true amphipathicity is much greater when considered as two segments joined by a flexible linker. We have selected a series of cecropin A 1–8 magainin 2 (1–12) hybrids that show significant structure activity relationships [280]. As shown in Figure 13, the helical wheel diagram places Ser 16 in cecropin A (1–8) magainin 2 (1–12) at the interface between the hydrophilic/polar face and the nonpolar face of the C-terminal amphipathic α helix. The effects on hemolytic activity of substitution of Ser 16 by a series of residues with increasing hydrophobicity (A < V < L < F < W) is shown in Table 5 (see Table 3 for the relative hydrophobicity differences of these residues). A large hydrophobe at position 16 can form $i$ to $i + 3$ and $i$ to $i + 4$ interactions with F13 and F20 to increase the hydrophobic surface area. As expected, the hemolytic activity increases with increasing hydrophobicity of the substituted residue (0% hemolysis for Ser and Ala at position 16 to 20.4% hemolysis at 100 μM for S16 W) (Table 5). Interestingly, the analog S16A, K12L compared to S16A increases hemolytic activity from

0% for S16A to 94.3% hemolysis at 100 μg/mL for S16A, K12L. S16A, K12L increases dramatically the hydrophobic surface area on the nonpolar face (Fig. 13), again demonstrating the effect of increasing hydrophobicity on hemolytic activity. All these peptides revealed a random coil structure in aqueous buffer but adopted α-helical structure in the presence of hydrophobic environments of TFE and SDS micelles. The three hydrophobic analogs at position 16 (Leu, Phe, and Trp) had potent antibacterial and antitumor activity but also concomitant with hemolytic activity [278]. The replacement of GIG by GPG in the hinge region of cecropin–melittin or cecropin–magainin hybrids had no effect on hemolytic activity but caused a drastic decrease in both antibacterial and antitumor activity [278] (Table 5). This suggests the importance of the conformation of the hinge region on these activities. On the other hand, replacing GIG in the hinge region with Leu in the S16L analog dramatically increased hemolysis from 11.8 to 88.6% hemolysis at 100 μ*M*. Replacement of GIG with Ser lowered hemolytic activity to 50% at 100 μ*M*, while replacement of GIG with Pro lowered the hemolytic activity to 3.6% at 100 μ*M* and retained both good antibacterial activity and antitumor activity. Thus, the GIG sequence and Pro must result in similar conformations of the hinge region.

### 4.2 De novo Designed Amphipathic α-Helical Antimicrobial Peptides

We have included in Table 6 representative examples of de novo designed amphipathic α-helical AMPs that emphasize key points about structure–activity relationships. The role of hydrophobicity/amphipathicity is clearly demonstrated by comparing the 12-residue peptides KAAAKWAAKAAK (peptide 1) and KLLLKWLLKLLK (peptide 2), where 7 alanine residues are substituted by 7 leucine residues [281]. In aqueous conditions, peptide 1 adopts a random-coil structure, whereas peptide 2 adopts substantial α-helical structure. When these two peptides were added to PE/PG vesicles, only the Leu-containing peptide adopted a predominantly α-helical structure. These results show the importance of hydrophobicity on the nonpolar face of a potential amphipathic α-helix to maintain α-helical structure. The amphipathicity also dramatically increases from 2.99 to 5.82 by increasing the hydrophobicity from Ala to Leu residues. The Ala peptide is essentially inactive against gram-negative and gram-positive organisms, whereas the Leu peptide dramatically enhances antimicrobial activity. The consequence of increased antimicrobial activity is a dramatic increase in hemolytic activity from 0 to 100% hemolysis at 100 μ*M* (Table 6). This demonstrates the importance of hydrophobicity and helical structure on antimicrobial and hemolytic activity, but peptide 2 shows no selectivity between prokaryotic and eukaryotic cells. Comparison of peptide 2 and peptide 3, where 4 D-Leu residues are substituted for 4 L-Leu residues, results in maintaining antimicrobial activity but significantly reducing hemolytic activity (<20% hemolysis at 100 μ*M*). The 2 peptides have the same inherent hydrophobicity; however, the mixing of D- and L-amino acid residues distorts the α-helical structure and amphipathicity. This suggests that the amphipathic α-helix is critical for disrupting eukaryotic membranes but not critical for activity in prokaryotic cells. The diastereomeric form of the peptide with a distorted helix in a hydrophobic environment may still be able to orient the hydrophobic face toward the hydrophobic part of the membrane and elicit antimicrobial activity [281]. Similarly, the 15-residue peptide (peptide 4) consisting of only Leu and Lys residues is extremely amphipathic (8.51) with excellent broad-spectrum activity against gram-positive and gram-negative organisms but no selectivity between prokaryotic and eukaryotic cells (100% hemolysis at 100 μ*M*) (Table 6) [282]. However, the incorporation of 5 D-amino acid residues (peptide 5) for the same L-amino acid residues results in excellent broad-spectrum activity and no hemolysis. In other words, distortion of α-helical structure has created outstanding selectivity. The same result is shown by comparing peptides 6 and 7 where peptide 6 has poor antimicrobial activity and is very hemolytic (80% hemolysis at 100 μ*M*) while peptide 7 with the incorporation of 4 D-Leu residues for 4 L-Leu residues results in removing hemolytic activity completely and dramatically enhancing antimicrobial activity [283]. Overall, these results suggest that AMPs can have high hydrophobic and positive charge density with excellent antimicrobial activity and cell selectivity as long as α-helical structure is distorted by incorporation of D-amino acid residues. The incorporation of D-amino acid residues also prevents peptide oligomerization and keeps the peptide monomeric. As discussed later, these results have implications for the mechanism of action of AMPs. Peptides 8–14 in Table 6 show a second approach to increasing cell selectivity by incorporation of a single Pro residue. Peptide 8 is the most amphipathic α-helix shown in Table 6 (9.70) with excellent antimicrobial activity but lacking cell selectivity (80% hemolysis at 50 μ*M*) [176]. Interestingly, substituting a Pro residue on the nonpolar face for a single Leu residue completely removes the hemolytic activity (peptide 9, Table 6). Similar results were observed when comparing peptide 10 with peptides 11 and 12 [284]. However, substituting a Pro residue for a Lys residue on the polar face of peptide 10 had no effect on reducing hemolytic activity (peptide 13). Hemolytic activity was reduced by using

[a]The amphipathicity is calculated in two segments, residues 1–9 and residues 10–18 or 10–20 or 10–26. The amphipathicity value for the two segments was averaged and reported in brackets. The average value divided by the total number of residues in the peptides gives the amphipathicity per residue.
[b]Minimum peptide concentration that produces hemolysis.
[c]Maximum peptide concentration that results in no hemolysis.

**Figure 13** Helical wheel representation of cecropin A hybrid α-helical antimicrobial peptides. Amphipathicity is indicated in brackets. The diagrams on the left show the hybrid peptides as a continuous helix and calculate the amphipathicity as a single helix. The figures on the right represent the hybrid peptides as two helical segments linked by a hinge region, and the amphipathicity values are shown for each segment. Gray denotes hydrophobic amino acids, dark gray denotes positively charged Lys residues, and white denotes hydrophilic residues, Gly, Thr, Ser and His.

D-Pro instead of L-Pro (peptide 14). Pro is known to disrupt α-helical structure in aqueous conditions and Pro has the lowest α-helical propensity value of all 20 amino acid residues (Table 3). Thus, distortion of α-helical structure by D-amino acid substitutions along the helix or a Pro substitution on the nonpolar face of an amphipathic α-helix are both effective at creating cell selectivity.

The last interesting result we observed on examining the activity profiles of de novo designed nonamphipathic cationic peptides was the dramatic enhancement of antimicrobial activity for both gram-negative and gram-positive organisms while maintaining cell selectivity when replacing 6 lysine residues by 6 arginine residues (peptides 15 and 16, Table 6) [285]. These effects of Arg are most likely due to its resonance-stabilized guanidinium group, which could lead to easier desolvation and more efficient ion-pairing with anions in the medium [124]. The difference in activity may be linked to differences in membrane lipid selectivity of Arg versus Lys side chains [286]. Interestingly, the occurrence of Arg and Lys in native antimicrobials in our database was 28

and 72%, respectively. These results suggest that the incorporation of Arg residues in amphipathic α-helical peptides instead of Lys residues may have an advantageous effect. Deslouches et al. [287] designed a 24-residue AMP composed of Arg (13 residues), Val (8 residues), and Trp (3 residues) with the sequence RRWVRRVRRWVRRVVRVVRRWVRR, arranged to form an idealized helical and amphipathic structure with a high net positive charge and high hydrophobicity. This peptide had high antimicrobial activity and minimal toxicity to mammalian cells (no hemolysis at 50 μ*M*). In animal studies, this peptide had a 50% lethal dose between 12 and 16 mg/kg. When *Pseudomonas*-infected mice [intrperitoneal (i.p.) with strain PAO1 at $1 \times 10^7$ to $1.5 \times 10^7$ colony-forming units (CFU)] were treated intravenously (i.v.) with 3 mg of peptide per kilogram body weight 30–45 min after administration of *P. aeruginosa*, no fatalities were observed; however, all untreated animals died by 40 h.

### 4.3 Enhancing Antimicrobial Activity and Removing Toxicity to Eukaryotic Cells

The major barrier to the use of AMPs as antibiotics is their toxicity or ability to lyse eukaryotic cells. To be useful as a broad-spectrum antibiotic, it would be necessary to dissociate antieukaryotic activity from antimicrobial activity, that is, increasing the antimicrobial activity and reducing toxicity to normal cells. An excellent measure of specificity is a parameter called therapeutic index, which is defined as the ratio of MHC (maximum peptide concentration that results in no hemolysis) and MIC (minimal inhibitory concentration or lowest peptide concentration that inhibited growth). A high value for the therapeutic index (MHC/MIC) means cell selectivity or specificity for bacteria over erythrocytes. For example, an MHC value of 500 μg/mL and an MIC value of 10 μg/mL would give a therapeutic index of 50. The therapeutic index (MHC/MIC) can be increased in one of the following three ways: increasing antimicrobial activity, decreasing hemolytic activity while maintaining antimicrobial activity, or a combination of both, that is, increasing antimicrobial activity and decreasing hemolytic activity. The vast majority of native AMPs are very hemolytic. However, hemolytic activity in amphipathic α-helical AMPs is related in a complex manner to hydrophobicity, amphipathicity, and net positive charge density (Table 1). With regard to amphipathicity, we have calculated overall amphipathicity based on the complete native sequence; however, it is clear that certain segments within the native sequence may be much more amphipathic. For example, BMAP-27 (bovine myeloid antimicrobial peptide-27) (1–27) has an overall amphipathicity of 5.23; however, its segment 1–18 has an amphipathicity of 8.30. Similarly, eCATH-1 (horse myeloid cathelicidin 1), a 26-residue AMP has an overall amphipathicity of 2.54, but the segment 1–17 has an amphipathicity of 4.65. Lycotoxin 1, a 25-residue AMP, has an overall amphipathicity of 1.17; however, segments 1–9 and 10–25 have amphipathicities of 6.26 and 2.35, respectively. Thus, structural determination is critical to determine if native AMPs contain one continuous α-helix in hydrophobic environments or have α-helical segments within the native sequence that are more amphipathic. Only with this information will it be possible to correlate amphipathicity with biological activity.

AMPs with low amphipathicity can have high hemolytic activity (e.g., histatin 5, amphipathicity of 2.26 and 50% hemolysis at 39 μ*M*) or low hemolytic activity (e.g., dermaseptin b1, amphipathicity of 2.79 and no hemolysis at 367 μ*M*). The relationship of net positive charge density and hemolytic activity is also complex. For example, BMAP-27 has a very high net positive charge density of 0.41 (+11 per 27 residues) while clavaspirin has a very low net positive charge density of 0.04 (+1 per 23 residues), yet both peptides are very hemolytic. On the other hand, PMAP-23 has a net positive charge density of 0.30 (+7 per 23 residues) with no hemolysis at 100 μ*M* (Table 1). Dermaseptin S9 has an interesting sequence. Its overall amphipathicity is low (1.87); however, the continuous hydrophobic segment 6–15 (IWLWVLLMIW) has an amphipathicity of 2.73. This peptide has the highest hydrophobic density (13.4) of all the AMPs listed in Table 1 and this may explain its high hemolytic activity (50% hemolysis at 175 μ*M*). Peptides with high hydrophobic density, high amphipathicity, and high charge density are very hemolytic. For example, BMAP-27 has a hydrophobic density of 11.2, an amphipathicity of 8.30 for 1–18, and a high net positive charge density of 0.41 and is very hemolytic (>80% hemolysis at 30 μ*M*) (Table 1). Clavaspirin has a very high hydrophobic density (11.7) and high amphipathicity of 6.61 for segment 1–10, which may explain its very high hemolytic activity, yet it has the lowest net charge density (0.04) (Table 1).

***C-Terminal Amidation Increases Antimicrobial Activity*** Removal of the C-terminal negative charge by amidation has been shown to improve antimicrobial activity for many native peptides [112, 288, 289]. For example, pleurocidin, a 25-residue peptide with broad-spectrum activity against a wide range of gram-positive and gram-negative bacteria (Table 1) when C terminally amidated showed a dramatic enhancement of antimicrobial activity [288]. On the other hand, though the amidated form of ascaphin-8 (19 residues) dramatically enhanced antimicrobial activity, hemolytic activity was

also enhanced (the concentration of peptide producing 50% hemolysis changed from >200 to 55 μ*M* for the C-terminal amidated form) [175]. This may be explained by the hydrophobicity of the C terminal (-VLF) of ascaphin-8 where the C-terminal negative charge would decrease the overall hydrophobicity, thus making the peptide less hemolytic.

***All-D Form of AMPs Increases Antimicrobial Activity*** The all-D form of AMPs has been shown to enhance antimicrobial activity in vitro and in vivo due to stability against proteolytic degradation [290, 291].

***Decreasing Hemolytic Activity by Shortening the Peptide Sequence of a Native AMP While Maintaining Antimicrobial Activity*** Examples of this approach are shown with bovine myeloid cathelicidins, BMAP-27 and BMAP-28 (bovine myeloid antimicrobial peptides-28). BMAP-27 is shown in Table 1. By removing the hydrophobic C-terminal tail and maintaining the complete N-terminal helix (residues 1–18), antimicrobial activity was maintained but the lytic effects on human red blood cells was lost in the case of BMAP-27 (1–18) [184]. These researchers also substituted the hydrophobic residues in the C-terminal tail of BMAP-28 from IIVPIIAI-amide with more hydrophilic ones (QATPATRQ-amide) and showed that this peptide did not have any significant lytic activity toward human red blood cells (3.3 versus 94.1% lysis at 100 μ*M* peptide). Their results showed a dramatic reduction of the lytic activity against mammalian cells when the C-terminal tail was removed or when substitutions in the C-terminal tail were carried out to decrease hydrophobicity [184]. Interestingly, these short peptides (1–18) were less effective in vivo than the full length peptides [292]. A second example of this approach is the shortening of the 26-residue melittin sequence. Melittin exhibits potent antimicrobial activity and potent hemolytic activity (Table 1) (100% hemolysis at 1 μg/mL). The 15-residue synthetic peptide corresponding to the C terminus (GLPALISWIKRKRQQG-amide) had about 5–7 times less antibacterial activity but 300 times less hemolytic activity (100% hemolysis at 300 μg/mL). Interestingly, changing the sequence to GL<u>KK</u>LISWIKR<u>AA</u>QQG-amide restored comparable antimicrobial activity to native melittin with only a marginal increase in hemolytic activity (100% hemolysis at 100 μg/mL) [293]. This degree of hemolysis is still unacceptable for a potential therapeutic but this result clearly shows the value of this approach.

***Substitution of Peptoid Residues on the Nonpolar Face of α-Helical Amphipathic AMPs to Reduce Hemolysis*** Peptoid residues are imino acids with their side chains shifted from the α carbon to the nitrogen position. These residues are thought to have a general helix-disrupting tendency due to the lack of an amide proton [294, 295]. Song et al. [296] showed that the incorporation of two alanine peptoid residues into the hydrophobic face of a model α-helical AMP significantly reduced hemolytic activity but not antimicrobial activity. In a recent study [138], peptoid residues were introduced into the nonpolar face of melittin at positions Leu 6, Leu 13, and Ile 20. Melittin has a minimal peptide concentration that produces hemolysis of 0.78 μ*M*. The peptoid residue-containing analogs of melittin caused no hemolysis at 100 μ*M* and were able to maintain antimicrobial activity within two-fold of native melittin. Thus, the therapeutic index was increased from 0.6 for melittin to 71 for the best peptoid analog (119-fold improvement). Certain peptoid analogs did not exhibit any cytotoxicity to mammalian cell lines. These peptoid analogs also had no α-helical structure in aqueous buffer, SDS micelles, or small unilamellar vesicles (SUVs) and showed no self-association ([138] and references therein) compared to melittin, which shows a concentration-dependent formation of an α-helical conformation. This reduction in hemolytic activity was due to a loss of structure and not a reduction in hydrophobicity since substitution of three Phe peptoid residues will have similar hydrophobicity compared to the original residues in melittin (Leu 6, Leu 13, and Ile 20). It is interesting that reducing hydrophobicity by substituting these three large hydrophobes in melittin with Lys peptoid residues and, thus, increasing the net charge from +6 to +9, maintained antimicrobial activity, while this peptide still had no hemolysis at 100 μM. Thus, the key seems to be disruption of α-helical structure since substitution by either Phe peptoid residues or Lys peptoid residues maintains antimicrobial activity.

***Changing Net Charge on the Polar Face*** Recently, Jiang et al. [297] showed that both the number of positively charged residues on the polar face and net charge are important for both antimicrobial activity and hemolytic activity. The most dramatic observation was the sharp transition of hemolytic activity on increasing one positive charge on the polar face from +8 to +9 in a 26-residue amphipathic α-helical AMP. The change from +8 to +9 resulted in a greater than 32-fold increase in hemolytic activity (250 μg/mL to <7.8 μg/mL, respectively). On the other hand, increasing the number of positively charged residues from 7 to 8 maintained the hemolytic activity at 250 μg/mL (maximal peptide concentration that produces no hemolysis of human red blood cells after 18 h) while showing an enhancement of antimicrobial activity [297]. Decreasing the number of postively charged residues on this 26-residue AMP from

7 to 4 made the peptide inactive against 6 different strains of *P. aeruginosa,* showing the importance of a minimum positive charge density for antimicrobial activity [297]. Similarly, adding 3 negatively charged residues to the polar face while maintaining the 7 positively charged residues (net charge +4) dramatically decreased antimicrobial activity while having no effect on hemolytic activity. This result emphasizes the importance of a minimum net positive charge density on antimicrobial activity [297]. The dramatic increase in hemolytic activity on increasing the net charge from +8 to +9 can be explained by the increase in net charge favoring the formation of transmembrane channels/pores in eukaryotic cells. The increase in net positive charge beyond +8 for the 26-residue peptide could stabilize the pore by increasing hydrophilicity of the pore [297].

***Decreasing Hemolytic Activity by Reducing Hydrophobicity While Maintaining Antimicrobial Activity*** The substitution of two Leu residues on the nonpolar face of melittin (Leu 6 and Leu 13) to Ala residues dramatically decreased hemolytic activity without impairing gram-positive and gram-negative activity. This analog is still induced into the α-helical structure in the hydrophobic environment of lipid vesicles but did not assemble into aggregates like the native melittin [298]. Decreasing hydrophobicity on the nonpolar face disrupts self-association and eliminates hemolytic activity. On the other hand, a peptide with excellent antimicrobial activity and extremely low hemolytic activity (no hemolysis at 500 μg/mL after 8 h; [132]) shows a systematic increase in hemolytic activity with a systematic increase in hydrophobicity of the nonpolar face (Fig. 17) [132]. Increasing hydrophobicity also increases antimicrobial activity until an optimum hydrophobicity is reached (Fig. 17, [132]) (see discussion later in Section 4.4, a general specificity determinant for amphipathic α-helical AMPs). Similarly, Lee et al. [299] designed analogs of PMAP-23 (Table 1) to increase fungicidal activity against pathogenic fungal cells. Three hydrophilic residues in the native peptide were substituted with Trp residues (R10W, Q13W, and K14W). These substitutions increased overall hydrophobicity (see hydrophobicity scale of [124]) and caused a dramatic increase in the fungicidal activity and antitumor activity. However, these authors did not report the hemolytic activity for this analog, which normally increases with increasing hydrophobicity, as shown in Fig. 17. Interestingly, two of the Trp substitutions lie between two Pro residues (PQKP in native PMAP-23 to PWWP in the analog). Since Pro residues disrupt the α-helical structure, the effect on amphipathicity cannot be calculated.

***Incorporation of Hinge Regions and Pro Residues Can Decrease Hemolytic Activity While Maintaining Antimicrobial Activity*** Hinge sequences like GIG or Pro have been shown to reduce or eliminate hemolytic activity dramatically (see Section 4.1 on hybrid amphipathic α-helical AMPs and de novo designed amphipathic α-helical AMPs). Hancock and co-workers [300] studied a series of α-helical AMPs without proline or with one or two prolines. Though the analogs with and without Pro were not identical in the remainder of the sequence, they were highly homologous. The peptide that lacked Pro exhibited the highest antimicrobial activity, with MICs of 0.5–4 μg/mL against all tested gram-negative and gram-positive bacteria, and was very hemolytic at 8 μg/mL (concentration required for lysis after 4 h was taken as the minimal hemolytic concentration). The peptide with a single Pro at position 12 had a hemolytic activity of >128 μg/mL with some loss in antimicrobial activity [300]. The native fowlicidin-1 and fowlicidin-3 have had their NMR structures determined in 50% trifluoroethanol. The peptides adopt a predominately α-helical structure with a slight kink induced by a Gly residue at position 16 of fowlicidin-1 and position 17 of fowlicidin-3 [51, 53]. However, these peptides still have very high hemolytic activity (Table 1). Obviously, Gly does not have the same effect on hemolytic activity compared to a hinge region like GIG or Pro.

***Reduction or Complete Removal of Hemolytic Activity by the Incorporation of D-Amino Acid Residues While Maintaining Antimicrobial Activity*** Melittin B, a 26-residue amphipathic α-helical AMP, is extremely hemolytic (100% hemolysis at 1 μg/mL) (Table 1). Substitution of 4 D-amino acids into the melittin sequence (D – $V^5$, $V^8$, $I^{13}$, and $K^{21}$) for their L-residues dramatically reduced α-helical structure in 40% TFE from 73% α-helical content for melittin to 15% for the above D-analog [190]. The D-analog lost its cytotoxic effects on mammalian cells and retained its antibacterial activity. NMR structural analysis on this D-analog revealed an amphipathic α-helix only in the C-terminal region of the diastereomer in TFE/water and methanol solutions and in DPC/DMPG (dimyristoyl phosphatidylglycerol) micelles [301]. ATR–FTIR experiments showed that melittin and the D-analog are oriented parallel to the membrane surface. They concluded that the N-terminal helix in melittin is crucial for binding and insertion into zwitterionic membranes and for hemolytic activity [301]. Thus, with a disrupted N-terminal helix hemolytic activity is lost. Chen et al. [302] made 19 L- and D- single amino acid substitutions in the center of a model amphipathic α-helix to determine the variation in helix disruption by each substitution in aqueous and hydrophobic conditions. Each single L-amino acid

substitution has a profound effect on α-helical structure under aqueous conditions. In contrast, in the presence of the α-helix inducing solvent TFE, the maximum α-helical content of the L-analogs was essentially the same, excluding Pro. All of the D-substituted peptides exhibited negligible secondary structure under aqueous conditions underlining the helix-disrupting properties of single D-amino acid substitutions. However, in the presence of 50% TFE these D-analogs (except for Pro) all exhibited considerable induction of α-helical structure similar to their L-counterparts. Thus, the disruption of α-helical structure by D-amino acid substitutions in a hydrophobic environment depends on the number of substitutions and the original helical propensity of the α-helix. The results of Chen et al. [302] showed the feasibility of controlled disruption of α-helical peptides by D-amino substitution in aqueous medium, while still allowing full folding in a more hydrophobic environment. We have also discussed the value of D-amino acid substitutions to remove hemolytic activity in the de novo designed amphipathic α-helical AMPs section above. In addition, we utilized single D-amino acid substitutions in amphipathic cyclic β-sheet and α-helical AMPs in the sections below.

***Substitution of a Single Positively Charged Residue in the Center of the Nonpolar Face of Amphipathic AMPs to Reduce Hemolysis*** This is discussed in Section 4.4.

### 4.4 A General Specificity Determinant of Cell Selectivity

Our approach was to show that a single substitution in the sequence of amphipathic cyclic β-sheet and α-helical AMPs with strong toxicity to human cells (as measured by hemolytic activity to erythrocytes) could generate specificity for prokaryotic cells.

***Amphipathic Cyclic β-Sheet AMPs*** Gramicidin S (GS) is a 10-residue, head-to-tail amphipathic cyclic peptide with the sequence Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro, consisting of 2 type II' β turns defined by Xxx-D-Phe-Pro-Xxx sequence with an amide bond between the N and C termini (Fig. 14). GS has excellent antimicrobial activity against gram-negative and gram-positive bacteria and yeast, as well as strong hemolytic activity (100% hemolysis at 12.5 μg/mL) [303]. In order to dissociate antimicrobial and hemolytic

**Figure 14** Structure of Gramicidin S and related analogs. (Left) Stick diagrams of cyclic β-sheet antimicrobial peptide gramicidin S. Dotted lines represent intramolecular hydrogen bonds. The bottom left shows the 4 hydrophobes (2 Val and 2 Leu residues on the top and 2 Orn residues on the bottom). (Right) Connolly surface representation of ring analogs GS14 (bottom) and GS14K4 (top) that has D-Lys substituted for L-Lys at position 4 (dark gray). Green represents the hydrophobic face (light gray).

activities, we developed a ring size analog of GS called GS14. This 14-residue amphipathic cyclic β-sheet peptide with the sequence Val-Lys-Leu-D-Tyr-Pro-Val-Lys-Leu-Lys-Val-D-Tyr-Pro-Leu-Lys had 6 large hydrophobes (3 Val and 3 Leu residues) on the nonpolar face and 4 lysine residues on the polar face. This peptide showed very weak antibiotic activity (>200 μg/mL) and extremely strong hemolytic activity (100% hemolysis at 1.5 μg/mL) for a very low undesired therapeutic index (MHC/MIC = 1.5 μg/mL/>200 μg/mL = <0.01). This analog represented an important milestone in our rational drug design approach in that we were able to dissociate antimicrobial and hemolytic activity. However, a true test of our ability to design an analog with potential clinical applications would be to invert the properties of GS14 and produce a compound with excellent antimicrobial activity but weak hemolytic activity (high therapeutic index). Nevertheless, this important study represented the first demonstration of the dissociation of antimicrobial and hemolytic activity in GS analogs, demonstrating that modulation of the biological activity of cyclic GS analogs could be achieved by variations in ring size [304]. Interestingly, GS14 bound to LPS with the highest affinity of the ring size analogs we prepared and with similar affinity to polymixin B [304]. The high affinity to LPS and the low antimicrobial activity suggested that the rigid β-sheet structure, high amphipathicity, and high positive charge of GS14 locked the peptide on the negatively charged surface of bacteria, thus preventing penetration of the peptide into the hydrophobic bilayer needed for antimicrobial activity. We reasoned that since amphipathicity is intimately linked to β-sheet structure in GS14, any change in β-sheet structure, for example, through disruption by substitution of residues with their enantiomers, would directly affect the amphipathicity of the molecule. We made a series of single enantiomeric substitutions where the peptides retained the same sequence, intrinsic hydrophobicity, and positive charge, differing only in structure. The extent of disruption of the β-sheet structure in the GS14 diastereomers was confirmed/demonstrated by both NMR and CD analyses of GS14 and GS14 analogs [303, 305]. This study was highly significant in demonstrating that a pre-formed highly amphipathic molecule in aqueous medium is not desirable in these cyclic peptides, since this results in decreased specificity and a low therapeutic index of GS14 as well as increased interactions with outer membrane components [303]. We identified a peptide called GS14K4 (D-Lys substitution for L-Lys at position 4 in the cyclic peptide) with a high therapeutic index (65 against *P. aeruginosa*, which is a 6500-fold improvement over GS14, which had a therapeutic index <0.01). There was a 133-fold decrease in hemolytic activity for GS14K4 compared to GS14. We were able to maintain or improve antimicrobial activity of our analog GS14K4 compared to GS while obtaining large increases in the therapeutic index (16- to 35-fold for gram-negative organisms and 8- to 33-fold for gram-positive organisms and 10-fold for the yeast *C. albicans* [303]. Structural studies by our group on GS14K4 in water and in the membrane mimetic solvent, trifluoroethanol, clearly showed the induction of β-sheet character in a membrane environment and the positioning of the charged side chain of D-Lys on the hydrophobic face of the cyclic framework (Fig. 14), which explains the decrease in amphipathicity and the decrease in effective hydrophobicity [305]. We then showed that it was possible to improve the therapeutic index of GS14K4 further, that is, improving the antimicrobial activity and/or decreasing the hemolytic activity or both by modulating the hydrophobicity on the nonpolar face [306]. These studies showed that the placement of a single positive charge in the center of the nonpolar face of a amphipathic cyclic β-sheet peptide dramatically altered specificity and decreased dimerization/oligomerization [127, 307]. The next question to be addressed was the generality of this specificity determinant (positively charged residue in the center of the nonpolar face). Therefore, we decided to take the same approach with amphipathic α-helical AMPs.

***Amphipathic α-Helical AMPs*** Our objectives were threefold: First, to test the hypothesis that disruption of α-helical structure in aqueous conditions by D-amino acid substitutions or substitutions of hydrophilic/positively charged L-amino acids on the nonpolar face can dramatically alter specificity in a similar manner to our results with cyclic β-sheet AMPs [303, 308]; second, to observe if these substitutions would enhance antimicrobial activity, decrease or eliminate toxicity, and improve antimicrobial specificity while maintaining broad-spectrum activity for gram-negative and gram-positive bacteria; and third, to demonstrate the importance of peptide self-association or lack of self-association in the activity of amphipathic α-helical AMPs. To test the above objectives, we selected an ideal candidate, a helical peptide with excellent antimicrobial activity and strong hemolytic activity from previous published research. The peptide referred to as V681 (Table 5A) resulted from semirandom DNA mutagenesis of an analog of a cecropin A (1–8) melittin B (1–18) hybrid [300, 309]. V681, a 26-residue peptide, was highly hemolytic (lysed human red blood cells at 8 μg/mL) and exhibited a very high activity against all gram-negative and gram-positive bacteria that were tested (MIC values ranging from 0.5 to 4 μg/mL) [300]. We previously demonstrated that the helix-destabilizing properties of D-amino acids offered a systematic approach to the controlled alteration of the hydrophobicity, amphipathicity, and helicity of amphipathic α-helical model pep-

tides. By single substitutions of different D-amino acids into the center of the nonpolar face of an amphipathic α-helical model peptide, we demonstrated that different D-amino acids disrupted α-helical structure to different degrees, while the destabilized structure could still be induced to fold into an α-helix in hydrophobic medium [302]. The advantage of the approach of single D- or L-amino acid substitutions at a specific site in the peptide is that it enables a greater understanding of the relationship of structure and mechanism of action of amphipathic α-helical AMPs. Chen et al. (2005) [130] chose D-/L-amino acid substitutions sites in the center of the nonpolar face (position 13) and polar face (position 11) of the helix of V681 (Figs. 15 and 16). The amino acid residues substituted at these positions represented a wide range of hydrophobicity from Leu > Val > Ala > Gly > Ser > Lys [124]. Leucine was used to replace the valine residue on the nonpolar face of V681 to increase peptide hydrophobicity and amphipathicity; alanine was selected to reduce peptide hydrophobicity/amphipathicity while maintaining high helicity; a hydrophilic amino acid, serine, was selected to decrease the hydrophobicity/amphipathicity of V681 in the nonpolar face; positively charged lysine was used to decrease further peptide hydrophobicity and amphipathicity. In our previous studies, we successfully utilized D-amino acid substitutions to remove the hemolytic activity of the cyclic β-sheet analogs [303, 305, 308]. In the V681 study, we also used D-enantiomers of the five L-amino acid residues Leu, Val, Ala, Ser, and Lys to change not only peptide hydrophobicity and amphipathicity but, more importantly, to disrupt peptide helical structure [130]. The results clearly showed that, for the nonpolar face substituted peptides, hemolytic activity was correlated with side-chain hydrophobicity of the substituting amino acid residues ($L_L > V_L > A_L > S_L > K_L$), that is, the more hydrophobic the substituting amino acid, the more hemolytic the peptide, consistent with our previous study on β-sheet AMPs [306]. For example, the maximum peptide concentration to show no detectable hemolytic activity (MHC value) for the $L_L$ substitution at position 13 (Fig. 15) was 7.8 μg/mL; in contrast, the MHC value was decreased, parallel with the reduction

**Figure 15** Helical wheels/helical nets representations of α-helical antimicrobial peptides V681 and V13K. The nonpolar face is indicated by circled hydrophobes (light gray) down the center of the helical net. The black bars between large hydrophobes indicate i to i + 3/i to i + 4 hydrophobic interactions. The positively charged Lys residues are boxed. The black arrow denotes position 13 the site for substitution.

**Figure 16** Space filling model of α-helical antimicrobial peptides V681 and V13K. White represents the peptide backbone; gray shows hydrophobic residues on the nonpolar face; light gray indicates amino acids included in the polar face; and the V13K substitution on the nonpolar face is colored dark gray.

of hydrophobicity, to an undetectable level for the peptide V13K (Fig. 15), a >32-fold decrease in hemolytic activity for V13K compared to V681 at 15.6 μg/mL. Peptide hydrophobicity and amphipathicity on the nonpolar face were also correlated with peptide self-associating ability; thus, peptides with less self-association in aqueous conditions also exhibited less hemolytic activity against eukaryotic cells [130]. In addition, peptide helicity seemed to have an additional effect on hemolytic activity. In general, on both the polar and nonpolar faces, D-amino acid substituted peptides were less hemolytic than their L-diastereomers. For example, $A_L$ at position 13 on the nonpolar face had an MHC value of 31.2 μg/mL compared to $A_D$ with a value of 250 μg/mL, an 8-fold decrease in hemolytic activity. This phenomenon generally correlated with peptide self-association ability since D-diastereomeric analogs exhibited weaker self-associating ability than L-analogs [130]. That is, D-substitutions disrupt helicity, which, in turn, disrupts hydrophobicity on the nonpolar face, which disrupts dimerization and decreases hemolytic activity. Thus, peptide structure is important in cytotoxicity toward mammalian cells, although these disrupted helices in aqueous conditions can still be induced into helical structure in the hydrophobic bilayer and still maintain antibacterial activity.

The antimicrobial activity of the two best peptides with nonpolar face amino acid substitutions against a range of gram-negative and gram-positive microorganisms is shown in Table 7. The two analogs with $K_L$ or $A_D$ substitutions on the nonpolar face showed a significant improvement (~3-fold) in antimicrobial activity against gram-negative bacteria when compared to peptide V681, which already had potent antimicrobial activity. For gram-negative bacteria, disruption of peptide helicity seemed to outweigh other factors in the improvement of antimicrobial activity, that is, in most cases, the peptides with D-amino acid substitutions showed better antimicrobial activity than L-diastereomers [130]. Compared to peptide V681, most of the peptide analogs with increased antimicrobial activity against gram-positive microorganisms were D-amino acid substituted peptides (data not shown; see [130]). The major change in activity profile of these two analogs was the reduction in hemolytic activity (Table 7), which has a dramatic effect on the therapeutic index. Peptide V13K showed a 90-fold and 17-fold improvement in the therapeutic index against gram-negative and gram-positive bacteria, respectively (Table 7). Peptide V13$A_D$ showed a 42-fold and 23-fold improvement in therapeutic index against gram-negative and gram-positive bacteria, respectively. From the helicity data of these peptides, it was clear that all peptides with improved therapeutic indices are those showing less stable helical structure in aqueous conditions (either D-amino acid substituted peptides or the hydrophilic/positively charged amino acid substituted peptides on the nonpolar face). It was noteworthy that the hemolytic activity of these two peptides was not detectable or was extremely weak. As noted above, we developed a novel technique to measure the self-association of small amphipathic molecules referred to as "temperature profiling in RP-HPLC." This technique was developed because we felt that dimerization/oligomerization of amphipathic AMPs in aqueous solution was an important factor in understanding overall antimicrobial activity. That is, the dimer/oligomer would have to dissociate to monomer to enter the hydrophobic environment of the bilayer, and it is the monomer that generates the antimicrobial activity. If the self-association ability of a peptide in aqueous media is too strong (forming dimers and burying the nonpolar face), it could decrease the ability of the peptide to dissociate and penetrate into the biomembrane and to kill target cells. In addition, if we can prevent dimerization in aqueous solution but still maintain the amphipathicity/hydrophobicity of the peptide in the bilayer, we would enhance activity. High peptide hydrophobicity, amphipathicity, and helicity usually

result in strong hemolytic activity. The controlled disruption of the α-helical structure (disruption under aqueous conditions and inducible in hydrophobic conditions) seems to be also related to strong antimicrobial activity in a variety of gram-negative and gram-positive bacteria.

It is generally accepted that increasing hydrophobicity of the nonpolar face of amphipathic α-helical peptides increases antimicrobial activity [310–312]. The striking result from our antibacterial assays was that hydrophobicity has two effects on peptide antimicrobial activity: at a relatively lower level of hydrophobicity, increasing peptide hydrophobicity caused an improvement in antimicrobial activity until an optimal hydrophobicity was reached; in contrast, peptide antimicrobial activity was weakened dramatically with further increases of hydrophobicity beyond the optimum, even resulting in dramatic loss of antimicrobial activity (Fig. 17) [132]. The reason for loss of antimicrobial activity at high hydrophobicity is that high hydrophobicity causes stronger peptide self-association/dimerization in solution, which in turn results in the monomer–dimer equilibrium favoring the dimer conformation. Peptide dimers are in their folded α-helical conformation and would be inhibited from passing through the capsule and cell wall to reach the target membranes compared to an unstructured monomer. In contrast, there is no polysaccharide-based cell wall in eukaryotic cells and increased hydrophobicity continues to increase hemolysis of human red blood cells where hydrophobicity of the bilayer causes rapid dissociation of dimers to monomers and entry into the bilayer to form channels/pores. In addition, the higher content of zwitterionic phospholipids and large amount of cholesterol in eukaryotic cell membranes compared to bacterial membranes may also supply a more hydrophobic environment, which would promote dimer-to-monomer dissociation and enhance hemolytic activity. The peptides used in Figure 17 are described in Chen et al. [132] where systematic increases in hydrophobicity were made by changing A12, A20, and A23 on the nonpolar face of V13K (Fig. 15) to Leu residues as single, double, and triple substitutions. Clearly, the placement of a lysine residue in the center of the nonpolar face destabilizes transmembrane helix formation in human red blood cells. However, the effect of this specificity determinant can be overridden by increasing the hydrophobicity of the nonpolar face of V13K (Fig. 15) by changing A12, A20, and A23 to Leu residues. The hemolytic activity then increases by 62.5-fold (no hemolysis at 250 μg/mL for V13K [132]. Increasing hydrophobicity allows transmembrane penetration of the helix by stabilizing pore/channel formation by increasing hydrophobic interactions of the hydrophobic surface of the pore/channel with the

**Figure 17** Relationship between peptide hydrophobicity, hemolysis (MHC), and antibacterial activity (MIC). (Top) The MIC values for six different strains of *P. aeruginosa*. The shaded panel shows the optimal hydrophobicity zone for antimicrobial activity. (Bottom) The MIC value plotted is based on the geometric mean of the MICs for the six *P. aeruginosa* clinical isolates versus peptide hydrophobicity. The arrow denotes the optimal antimicrobial activity. MHC is the maximal peptide concentration that caused no hemolysis of human erythrocytes after 18 h. MIC is the lowest peptide concentration that inhibits growth after 24 h [132].

hydrophobic lipid. Similarly, increasing hydrophilicity/positive charge on the polar face can also stabilize transmembrane pore formation [297]. Thus, it seems reasonable to propose that both surfaces of a transmembrane pore/channel could contribute to formation and stability of such a pore/channel. Stability of such a pore/channel is dependent on the hydrophobicity of the nonpolar face and hydrophilicity of the polar face.

Factors believed to be important for antimicrobial activity have been identified and include peptide hydrophobicity, the presence of positively charged residues on the polar face, amphipathicity that segregates basic and

hydrophobic residues to opposite sides of the molecule and secondary structure. Our laboratory has added to this list, which includes: (1) the importance of lack of structure in aqueous conditions but inducible structure in the presence of hydrophobic environment of the membrane; (2) the presence of a positively charged residue in the center of the nonpolar face of amphipathic cyclic β-sheet and amphipathic α-helical AMPs as a determinant for locating peptides to the interface region of prokaryotic membranes and decreasing transmembrane penetration into eukaryotic membranes; (3) the importance of peptide self-association in aqueous environment to biological activity; and (4) we have recently shown that if the surface hydrophobicity is too large the peptides actually become less active, that is, increasing hydrophobicity decreases antimicrobial activity at some point, which is due to increased dimerization/self-association [132]. It is interesting that nature did not design AMPs for selectivity (i.e., to be nontoxic to human cells). Our de novo designed specificity determinant (positively charged Lys residue in the center of the nonpolar face) achieves three goals at once: (a) prevents dimerization in aqueous solution; (b) disrupts the secondary structure in aqueous solution; and (c) provides specificity for prokaryotic cells. We hypothesize that the disruption of secondary structure and keeping the peptide monomeric allows the peptide to more easily pass through the capsule and cell wall to reach the membrane and allows the secondary structure to be induced in the hydrophobic environment of the bilayer, which is critical for antimicrobial activity. Our de novo designed determinant of specificity has not been observed in any AMPs to date, and that is why we believe it is such a key discovery to the development of AMPs as therapeutics.

***Proposed Mechanism for Cell Selectivity of Amphipathic Cyclic β-Sheet and α-Helical AMPs*** We have proposed a "membrane discrimination mechanism" of action for amphipathic cyclic β-sheet and amphipathic α-helical AMPs whose sole target is the biomembrane to explain peptide specificity between prokaryotic and eukaryotic membranes. Peptide specificity depends upon the compositional difference in the lipids between the two types of membranes where eukaryotic cell membranes, in contrast to prokaryotic membranes, are generally characterized by zwitterionic phospholipids, a relatively large amount of cholesterol and sphingomyelin, and the absence of the high, inside negative transmembrane potential that is present in prokaryotic membranes. The outer surfaces of bacterial membranes are devoid of cholesterol and contain significant amounts of negatively charged (anionic) phospholipids in the outer leaflet of the lipid bilayer [268, 313, 314]. Our membrane discrimination mechanism is based on a "barrel-stave" mechanism [228] in eukaryotic cells and a "carpet" mechanism [233, 315] in prokaryotic cells. This model proposes that hemolysis of human red blood cells by amphipathic α-helical peptides requires insertion of the peptides into the membrane, perpendicular to the membrane surface, and interaction of the nonpolar face of the amphipathic α-helix with the hydrophobic lipid core of the bilayer while the hydrophilic charged surface of the polar face points inward, producing an aqueous transmembrane channel/pore (barrel-stave mechanism). In contrast, amphipathic α-helical peptides with cell selectivity produce antimicrobial activity in prokaryotic cells by lying at the membrane interface parallel with the membrane surface; interaction of the nonpolar face of the amphipathic α-helix with the hydrophobic component of the lipid and interaction of polar/positively charged face with the negatively charged head groups of the phospholipids causes membrane disruption in a detergent-like mechanism as described in the carpet model. In support of this proposal, we have selected two examples from the study of Chen et al. [130]. Peptide V13K (in its all-D form) (Figs. 15 and 16), which has Lys in the center of the nonpolar face shows no hemolysis at 500 μg/mL after 8 h [131] (Fig. 11) yet has excellent broad-spectrum antimicrobial activity [130, 131]. If hemolysis of human red blood cells requires transmembrane insertion of the peptide in the membrane, it seems reasonable to assume that disruption of the hydrophobic surface with a positive charge in the center of the nonpolar face would prevent penetration into the hydrophobic core of the membrane. Thus, no hemolysis for V13K. On the other hand, if the mechanism for antimicrobial activity in prokaryotic cells does not require transmembrane insertion of the peptide into the hydrophobic bilayer, then the peptide can locate to a much lower hydrophobic environment in the interface region and still effectively disrupt the membrane. In contrast to V13K, this same sequence with a Leu substitution at position 13 instead of Lys results in poorer antimicrobial activity (MIC values of 12.7 μg/mL of V13L versus 3.1 μg/mL for V13K against gram-negative bacteria) and stronger hemolytic activity (7.8 μg/mL for V13L versus no detectable hemolytic activity for V13K), which can also be explained by our combined model. Peptide V13L has a continuous nonpolar face and greater hydrophobicity of the nonpolar face than V13K. Thus, it can insert transmembrane into the red blood cell membrane, causing significant hemolysis. Because of the properties of V13L, it actually interacts less with the water–lipid interface region of the bacterial membrane (it is not restricted to this preferred location), hence the antimicrobial activity is fourfold weaker than V13K against gram-negative bacteria. This

supports the view that the carpet mechanism is essential for strong antimicrobial activity and, if there is a preference by the peptide for deep penetration into the hydrophobic core of the bilayer, the antimicrobial activity will actually decrease.

### 4.5 Enhancing Stability

In 1990, Merrifield and co-workers [279] were the first to show that the all-D enantiomers of naturally occurring AMPs, cecropin A, magainin 2 amide, and melittin along with cecropin–melittin hybrid peptides were structurally identical to their L-counterparts as shown by circular dichroism measurements, but the ellipticities were of opposite sign. In addition, in all the isomeric pairs of peptides, the antimicrobial activity of the D-enantiomer was quantitatively equivalent to that of the L-enantiomer. This suggested that the antimicrobial activity does not involve a stereoselective interaction with a chiral enzyme or lipid or protein receptor. The major advantage of the D-enantiomers is their resistance to enzyme degradation. In cases where the L-enantiomers have been shown to be significantly less active than the D-enantiomer, the differences implicated the stability of the D-enantiomer to proteolytic enzymes produced by the organisms. The above results have been well documented for many other AMPs ([131, 279, 291, 316–322]). From Fig. 18, the CD spectra are shown for two pairs of L- and D-enantiomers. The substitution of a lysine residue in the center of the nonpolar face of the peptide V681 completely abolished α-helical structure in aqueous conditions (50 m*M* potassium phosphate buffer containing 100 m*M* KCl) but allowed the α-helical structure to be induced in the presence of a hydrophobic environment, 50% trifluoroethanol in aqueous buffer. As discussed earlier, the incorporation of D-amino acids into an L-peptide can be effective at inducing selectively between eukaryotic and prokaryotic cells, but the all D-enantiomers are much preferred because of their stability to proteolysis.

Casteels and Tempost [113] showed that the all-D enantiomer of apidaecin is completely devoid of antibacterial activities, which suggested that the effects of apidaecin involve a stereoselective recognition of a chiral cellular target. This peptide was functionally unique among insect antibacterials. Apidaecin, an 18-residue peptide, had a unique sequence of 33% proline residues (GNNRPVYIPQPRPPHPRL).

**Figure 18** Circular dichroism (CD) spectra of V681 and D-V681 (Top) and V13K$_L$ and D-V13K$_D$ peptides (Bottom). Circles denote L-peptides and diamonds denote D-peptides. Solid symbols show spectra obtained for peptides in 50 m*M* aq. potassium phosphate buffer containing 100 m*M* KCl without triflouroenthanol (TFE), and open symbols show spectra collected in the presence of aqueous buffer containing 50% TFE. (See [131] for more detail.)

## 5 THERAPEUTIC DEVELOPMENT (PRECLINICAL AND CLINICAL STUDIES)

During 2005, 8987 cases of invasive MRSA with 1598 associated deaths were reported in the United States [323]. New classes of antibiotics are needed to protect against the growing MRSA threat and other challenging infections such as *P. aeruginosa* in cystic fibrosis patients and candidiasis in persons with AIDS. AMPs represent a relatively new therapeutic class with potential impact in these areas. Not surprisingly, academic and industrial interest in therapeutic development of AMPs continues to grow. The development record of AMPs has been mixed to date (Table 8). Late-stage trials of Intrabiotics' peptide Iseganan for ventilator-associated pneumonia were halted for safety concerns, and Xoma's rBPI$_{21}$ failed to reach statistically significant efficacy in a phase III trial. However, select AMPs have successfully completed clinical development, gained regulatory approval, and entered the clinic. Polymyxin B is currently used in multiple topical and ophthalmic therapies including Polysporin First Aid Antibiotic Ointment and Neosporin Ophthalmic Solution. In the antiviral area, Trimeris' peptide Enfuvirtide defined the viral fusion

**TABLE 8 AMPs in Clinical Development**

| Peptide/Product | Company | Indication | Development Stage |
|---|---|---|---|
| | | *Marketed* | |
| Enfuvirtide/Fuzeon | Trimeris | HIV | Approved |
| Polymyxin B | Pfizer | Bacterial eye infection, *P. aeruginosa* infection | Approved |
| | | *Clinical Development* | |
| MBI-226 | Migenix/Cadence Pharmaceuticals | Wound/burn/device-related infection | Phase III completed |
| $rBPI_{21}$/Neuprex | Xoma | Severe meningococcal sepsis | Phase III inconclusive |
| Iseganan | Intrabiotics/Pacgen | Ventilator-associated pneumonia | Failed phase III |
| P113 | Demegen/Pacgen | Lung infections in CF, Oral candidiasis in immunocompromised | Phase II complete |
| hLF-11 | AM-Pharma Holding | 1. Prevention of infections during hematopoietic stem cell transplant | 1. Phase IIa |
| | | 2. MRSA/MRSE | 2. Phase I completed |
| | | 3. Candida | 3. Phase I completed |

inhibitor therapeutic class to block HIV entry into CD4 T cells. Given the variety of structural peptide motifs available for rational drug design and the low natural bacterial resistance, preclinical and clinical investigations will continue to explore possible AMP therapeutic applications.

## ACKNOWLEDGMENT

# ANTIBODIES FOR HUMAN DISEASES

Guo-Liang Yu[1] and Jian Ni[2]
[1]Epitomics, Inc., Burlingame, California, [2]Human Antibodomics Limited, Shanghai, China

## 1 PRINCIPLE OF MONOCLONAL ANTIBODY THERAPY

The immune system is our defense system that prevents us from illness and also works to help our recovery from many illnesses. The immune system plays a central role in protecting the body against various diseases such as infectious diseases, inflammation, and cancer. It is also the major force in the body in combating diseases that have already developed. The body's ability to develop an immune reaction to tumors may help determine which patients are cured of cancer using conventional therapies, including surgery, radiation, and drugs. The concept of immunotherapy is based on the body's natural defense system, which protects us against a variety of diseases [1].

Many years of research have resulted in the successful examples of immunotherapies for many diseases including cancers and inflammatory diseases. These new treatments referred to as biological therapies—such as monoclonal antibodies and vaccine therapies. The recent technological advances in monoclonal antibody (mAb) development caused significant investment and interest in the pharmaceutical and biotech industry. It is estimated that nearly half of all clinical trials are conducted on monoclonal antibodies [2]. Antibodies are complex protein molecules that are a component of the immune system. These molecules belong to the immunoglobulin (Ig) class of proteins. They are a major component of the body's adaptive immune system, which is involved in mounting a specific attack against "foreign" molecules, cells, and organisms by recognizing and binding to antigens. The cells that produce antibodies are known as B cells.

There are several classes of antibodies in humans including the IgG class (IgG1, IgG2, IgG3, and IgG4), IgM, IgA class, IgD, and IgE. IgG is most abundant class of antibodies with serum concentration of 10%. All therapeutic antibodies are IgG molecules, typically IgG1 or IgG2. The structure of antibodies is Y-shaped, consisting of two light chains and two heavy chains, which are linked by disulfide bonds (Fig. 1). The light and heavy chains contain a variable region, also known as the Fab (fragment antigen binding) region, and a constant region, which is also known as the Fc (fragment crystallizable) region. The Fab region is the main part of the molecule involved in antigen recognition. This region is encoded by genes that can be rearranged to achieve the extensive diversity of antigen recognition. The constant region, on the other hand, is involved in inducing the effector functions of antibodies and mediating an immune response [3].

High specificity, high affinity to a disease target and relatively low or no effect on other substance except the target antigen make mAb ideal molecules for therapeutic agents. Monoclonal antibodies are suited to target different target molecules and may offer different action mechanisms. In addition, it is possible to modify and improve an antibody drug candidate by genetic engineering methods and establish large-scale production using recombinant protein technology.

## 2 HISTORY OF ANTIBODY THERAPEUTICS

The history of antibody therapeutics is an evolution of antibody engineering to produce antibodies with less and less immunogenicity reaction in humans. Figure 2 illustrates the four types of monoclonal antibodies from pure murine to partial human and from partial human to full human. Köhler and Milstein developed the hybridoma method of murine antibody production in 1975 [4], which won the Nobel Prize and allowed the production of the first mAb to market. In 1986, Johnson & Johnson developed Orthoclone OKT3 (muromonab) for the treatment of renal allograft rejection resistant to steroid and antilymphocyte globulin [5]. However,

**Figure 3** U.S. approved therapeutic mAbs.

murine antibodies are from mice and the application of murine antibodies was extremely limited in humans because it caused an immunogenicity reaction, known as the HAMA (human antimouse antibodies) response. When administered to humans, murine antibodies cause serious side effects, including anaphylaxis and hypersensitivity reactions. This immunogenicity reaction is triggered by the human immune system recognizing the molecules as foreign because murine antibodies are different from natural human antibodies. In addition, murine monoclonal antibodies consequently have a short half-life relative to human antibodies.

In 1984, the first chimeric antibodies, where 30–35% of the molecule is derived from mouse antibody sequences and around 65–70% is derived from human antibody sequences, were reported [6, 7]. Chimeric monoclonal antibodies are generated by using recombinant deoxyribonucleic acid (DNA) technology, where the murine Fab region is fused to the human Fc region of an antibody. Chimeric antibodies turned out to be more successful therapeutic agents than murine monoclonal antibodies in overcoming the immunogenicity problems. The two most successful monoclonal antibody therapies in 2004, Biogen Idec/Genentech/Roche's Rituxan (rituximab) and Johnson & Johnson/Schering-Plough's Remicade (infliximab), are both chimeric. Their success has been attributed to the lack of immunogenicity reactions, as well as successful target selection. However, as a substantial portion of chimeric monoclonal antibodies are murine, there is still a considerable risk of the human immune system recognizing the molecules as foreign and eliciting an immunogenicity reaction, known as HACA (human antichimeric antibody) responses [3].

To mitigate this, the next technological development after chimeric antibodies to minimize immunogenicity reactions was humanization technology [3, 8]. Using protein engineering technologies, it can generate monoclonal antibodies where 90–95% of the sequences are of human origin. Human antibody generates about 10% diversity in the antibodies protein sequences during the antibody maturation process by gene splicing and mutations. Therefore, the remaining 5–10% nonhuman portions in the humanized antibodies become much tolerable in humans. The humanization technique initially uses genetic engineering to transfer the murine antigen-binding sequences, known as the complementarity-determining region (CDR), to a human antibody scaffold. The CDR region is part of the Fab region, which carries the antigen-binding specificity.

The CDR sequences transferred are usually optimally selected to those that confer the binding specificity and biological function, keeping murine sequences to a minimum in the resultant monoclonal antibodies. A number of techniques are now used for humanization or deimmunization. As a result of the fewer murine sequences, these molecules carry a lower risk of triggering an immunogenicity reaction than chimeric and murine antibodies. Humanized antibodies, like chimeric monoclonal antibodies, carry the ability to effectively induce immune responses because of the Fc region is humans. Most of antibody drugs on the market and in clinical development are humanized antibodies.

The initial methods for humanization are time consuming and costly. Advanced technologies such as Epitomics' "HuRAb technology" bring significant improvement for the humanization process (unpublished). HuRAb technology utilizes the sequence information in the antibody evolution to correlate rabbit monoclonal antibody sequences and their biological functions. Alignment of sequences of antibodies that derive from the same antibody maturation process and possess the same biological function allows the identification of residues that are critical to the functions of the antibodies and systematically convert the noncritical residues to human residues, resulting in a higher degree of homology to human antibody. Such a process can be accomplished within 2 weeks by one researcher compared with the almost 1-year effort using traditional methods.

To further minimize the effort to humanize murine antibodies, technologies were developed to generate human antibodies directly. Transgenic mice have had their innate antibody genes replaced by human antibody genes, while leaving intact the other components of the mouse immune system [3, 9]. As a result the transgenic mice produce human antibodies in response to immunization with an antigen. Once the mouse has been immunized, mAbs can either be generated through traditional hybridoma generation or by using technologies that involve the harvesting, plating, and screening of B cells, followed by isolation of mAb genes and cloning into production cell lines. One example of such success is panitumumab (anti-epidermal growth factor [EGF]) of Amgen (Abgenix). Another approach to generate human antibody is to screen a phage library generated using human antibody genes. Phage display involves the engineering of bacteriophages to display human monoclonal antibodies on their surface. Genes from human antibody gene libraries are inserted into a library of phage. Each phage carries the genes for a different antibody and displays a different antibody on its surface. Antibodies are selected for binding to a target antigen. The corresponding genes that encode the antibody protein can be recovered. Adalimumab [tumor necrosis factor-α (anti-TNF-α)] is the first human antibody developed by Abbot and AstraZeneca (Cambridge Antibody Technology) using phage display technology.

The traditional therapy areas for mAb therapy are oncology and autoimmune and inflammatory disorders. It is also anticipated that mAb therapy will play a role in infectious diseases, cardiovascular diseases, as well as degenerative diseases. The high level of innovation, as demonstrated by advancements in antibody engineering with the introduction of chimeric, human mAbs, lead the way for this new class of therapeutics to become a major class of modern medicine. Other innovations in antibody technology include advancements in developing small-sized antibody molecules, enhanced affector function, and multifunctional antibodies such as bispecific antibodies lead to a huge boost in developing drugs that utilize these technologies [9]. Table 1 list all monoclonal antibodies launched on the market by time and by class.

In summary, the driver of antibody industry growth to be considered is the evolution of antibody technology. Although murine monoclonal antibodies were the first class of mAbs to enter clinical trials, these molecules have failed to become a major class of therapeutic antibodies due to the immunogenicity problems they cause. As a result, chimeric and humanized antibodies have dominated the industry's marketed products. There is a level of interest at the research and development (R&D) level across all phases to develop human mAbs. While technology of antibodies has been a key factor in the success of the market to date, the therapeutic suitability of antibodies for the treatment of immune-related diseases, cancer, and infectious disease is also expected to continue to drive new innovations. Historically, the monoclonal antibody development has been led by new antibody engineering technologies.

## 3 ANTIBODY TECHNOLOGY

### 3.1 Murine Hybridoma

The first type of monoclonal antibodies that could be generated is murine monoclonal antibodies. Köhler and Milstein developed the Nobel-Prize-winning hybridoma technique in 1975, which can be used to produce cell lines capable of producing identical antibodies indefinitely [3, 4]. The technology generates cells called hybridomas that can multiply indefinitely having the characteristics of B cells, which produce antibodies, and myeloma cells, which can divide indefinitely. A hybridoma is created by fusing a B cell with a myeloma cell using either a chemical [polyethylene glycol (PEG)] or physical (electrofusion) method. This development marked a major breakthrough in the development of monoclonal antibodies as therapeutics, diagnostics, and research reagents.

The ability to produce monoclonal antibodies led to the investigation of these molecules as therapeutic agents, using them to either mimic natural human antibodies or to interfere with biochemical pathways through receptor interaction. Unfortunately, it was found that murine mAbs caused an immunogenicity reaction, known as the HAMA (Human Anti-Mouse Antibodies) response which causes serious side effects including anaphylaxis and hypersensitivity reactions,

**TABLE 1 U.S. FDA Approved Therapeutic mAbs**

| Ab and Target | Product | Company | Preparation | Approved | Indication |
|---|---|---|---|---|---|
| Muromomab-CD3 (anti-CD3) | Orthoclone OKT3 | Ortho Biotech J&J | Murine hybridoma | 1986.6 | Kidney-transplant rejection |
| Abciximab (anti-GPIIb/IIIa) | ReoPro | Centocor | NSO (Chimeric) | 1994.12 | Coronary angioplasty |
| Rituximab (anti-CD20) | Rituxan Mabthera | Roche/IDEC/Genentech | CHO (Chimeric) | 1997.11 | Non-Hodgkin's lymphoma |
| Daclizumab (anti-CD25) | Zenapax | Hoffman–La Roche | CHO (Humanized) | 1997.12 | Kidney-transplant rejection |
| Basiliximab (anti-CD25) | Simulect | Novartis | NS0 (Chimeric) | 1998.5 | Kidney-transplant rejection |
| Palivizumab (anti-F protein of RSV) | Synagis | Medlmmune | NSO (Humanized) | 1998.6 | RSV |
| Infliximab (anti-TNFα) | Remicade | Centocor | NSO (Chimeric) | 1998.8 | Crohn's disease, ra |
| Trastuzumab (anti-HER-2) | Herceptin | Roche/Genentech | CHO (Humanized) | 1998.9 | Breast Cancer |
| Etanercept (anti-TNFα) | Enbrel | Immunex/Wyeth | CHO (Fc fusion) | 1998.11 | RA |
| Gemtuzumab ozogamicin (CD33) | Mylotarg | Wyeth/AHP | NSO (Humanized) | 2000.5 | CD33+ acute myeloid leukemia |
| Alemtuzumab (anti-CD52) | Campath | Millennium/ILEX | CHO (Humanized) | 2001.5 | B-cell chronic lymphocytic leukemia |
| Ibritumomab tiuxetan (anti-CD20) | Zevalin | Biogen IDEC | CHO (Murine) | 2002.2 | Non-Hodgkin's lymphoma |
| Adalimumab (anti-TNFα) | Humira | Abbot Laboratories/CAT | CHO (Phage display, human) | 2002.12 | RA |
| Alefacept | Amevive | Biogen IDEC | CHO (Fc Fusion) | 2003.1 | Plaque psoriasis |
| $^{1}$131 Tositumomab (anti-CD20) | Bexxar | Corixa Corp. and GlaxoSmithKline | NS0 (Murine) | 2003.6 | Non-Hodgkin's lymphoma |
| Omalizumab (anti-IgE) | Xolair | Genentech/Tanox/Novartis | CHO (Humanized) | 2003.6 | Persistent asthma |
| Efalizumab (anti-CD11a) | Raptiva | Xoma/Genentech | CHO (Humanized) | 2003.1 | Plaque psoriasis |
| Cetuximab (anti-EGFR) | Erbitux | Imclone/BMS | NS0 (Chimeric) | 2004.2 | Metastatic colorectal cancer |
| Bevacizumab (anti-EGFR) | Avastin | Genentech | CHO (Humanized) | 2004.2 | Metastatic colorectal cancer |
| Natalizumab (α-4-integrin) | Tysabri | Biogen Idec/Elan Pharmaceuticals | NS0 (Humanized) | 2004.11 | Multiple sclerosis |
| Ranibizumab (anti-VEGF) | Lucentis | Genentech | E. coli (Humanized) | 2006.6 | Neovascular (wet) age-related macular degeneration |
| Panitumumab (anti-EGFR) | Vectibix | Amgen | CHO (Xenomice, human) | 2006.9 | Metastatic colorectal cancer |
| Eculizumab | Soliris | Alexion | NS0 (humanized) | 2007.3 | Paroxysmal nocturnal hemoglobinuria (PHN) |

when administered to humans. This immunogenicity reaction is triggered by the human immune system recognizing the molecules as foreign because the murine antibodies are different from natural human antibodies, at structure and sequence levels. In addition, murine monoclonal antibodies consequently have a short half-life because the human immune system recognizes murine antibodies as foreign. As a result of these issues, none of the many murine monoclonal antibodies was able to be used in clinic and there is only one marketed

murine monoclonal antibody, muromonab (OrthoClone OKT3). Consequently, there is no interest in using this technology to develop therapeutic agents, especially with the advancement in technology to produce more human-like antibodies. The use of murine antibodies is now largely focused on use as diagnostic and research agents, where immunogenicity issues are not an issue.

### 3.2 Humanized Antibodies

The next technological development after chimeric antibodies to minimize immunogenicity reactions was humanization technology. This can be used to generate monoclonal antibodies where 90–95% of the sequences are of human origin and 5–10% are of murine origin. The technique uses genetic engineering to transfer the murine antigen-binding sequences, known as the complementarity-determining region (CDR), to a human antibody scaffold [3, 8]. The CDR is part of the Fab, which carries the antigen-binding specificity. The CDR sequences transferred are usually optimally selected to those that confer the binding specificity and strength, keeping murine sequences to a minimum in the resultant monoclonal antibodies. As a result of the fewer murine sequences, these molecules carry a lower risk of triggering an immunogenicity reaction than chimeric and murine antibodies.

There are a number of antibody technology platforms that can be licensed to develop humanized antibodies. The key players include Protein Design Labs' SMART humanization technology, Aeres Biomedical's humanization technology, and Xoma's human engineering technology. However, developing humanized antibodies can be time consuming and engineering humanized monoclonal antibodies can be expensive. Most importantly, humanization can reduce binding affinity because certain murine sequences involved in binding strength may not be transferred to the final antibody molecule. As a result of this, sequence selection needs to be carefully done to ensure that binding affinity and biological activities are not reduced substantially.

Recently, a new humanization technology was developed by Epitomics termed HuRAB technology, which is designed to overcome the limitation of traditional humanization technology. The HuRAb technology utilizes information of genetic evolution of the rabbit immune system: B-cell maturation, to optimize and at the same time convert a rabbit monoclonal antibody to human antibody molecule. The cost and time to engineer an antibody is significantly reduced. Furthermore the resulting antibodies remain and sometimes have improved binding capability than their parental antibody molecules.

Developing humanized antibodies can be time consuming because murine antibodies specific to the antigen need to be developed before humanization can be carried out. Secondly, as a result of this, engineering humanized monoclonal antibodies can be expensive. Thirdly, and most importantly, humanization can reduce binding affinity because certain murine sequences involved in binding strength may not be transferred to the final antibody molecule. As a result of this, sequence selection needs to be carefully done to ensure that binding affinity and biological activities are not reduced substantially.

### 3.3 Rabbit Hybridoma

Rabbits are one of the best sources of high-affinity polyclonal antibodies. Traditionally, it has been difficult to raise monoclonal antibodies in the rabbit. The most efficient and practical way to immortalize antibody-secreting B lymphocytes is by fusing lymphocytes obtained from spleen or lymph node with myeloma cells. Myeloma cells are derived from a B-cell tumor that arises in mice and humans, but not in rabbits. These fusions result in hybrid cells, called hybridomas, which often maintain the differentiated properties of antibody-secreting plasma cells, while gaining the ability to multiply indefinitely in culture (Fig. 4). Since myeloma-like tumors were not available in the rabbit, it has been impossible to use this approach to raise rabbit monoclonal antibodies. Several laboratories developed mouse–rabbit heterohybridomas, but this technology has had limited success. The earliest mouse–rabbit heterohybridomas were unstable and some only secreted light chains [10–13]. Recombinant antibody approaches reported that rabbit monoclonal antibody genes were isolated from single-cell polymerase chain reaction (PCR) or phage display [14, 15]. However, its general application is limited by the difficulty of single-cell selection and PCR, or by technically demanding protocols of phage display.

In 1995, Katherine Knight and colleagues succeeded in producing a myeloma-like tumor (plasmacytoma) in transgenic rabbits expressing the *v-abl* and *c-myc* oncogenes under the control of the immunoglobulin heavy- and light-chain enhancers, respectively [16] . These researchers isolated a plasmacytoma cell line, termed 240E, and showed that fusions of 240E cells with rabbit lymphocytes produced stable hybridoma.

The availability of rabbit monoclonal antibodies is highly desirable [17]. First, antisera from rabbits are generally of higher affinity than the equivalents in mice. Preliminary result from Epitomics indicated that the binding affinity of rabbit monoclonal antibodies can be 100 times better (unpublished data). Second, rabbit monoclonal antibodies are expected to recognize many

**Figure 4** Rabitt hybridoma.

antigens that are not immunogenic in mice, including mouse proteins [18–22]. For example, Bystryn et al. [19] compared rabbit and mouse antibodies directed against human melanoma cells and showed that they recognize different epitopes [19]. Third, Because the size of the rabbit spleen, more fusion experiments can be performed, making hybridoma generation at industrial scale a feasible task. Epitomics, Inc. has exclusively licensed 240E cell line from Loyola University and has developed a 240E derivative cell line that is highly stable and productive.

### 3.4 Human Hybridoma

Human antibodies are derived either from vectors carrying human antibody genes or from human cells. Human antibodies, therefore, theoretically have minimal immunogenicity. The difference between humanized and human mAbs is very small, since humanized antibodies already go virtually undetected by the human immune system because the antibodies produced by human differ by 10% themselves. Human monoclonal antibodies are still perceived to have favorable safety profiles and be eliminated less rapidly from the human body, potentially reducing the frequency and amount of dosing required. However, this is based on the assumption that the human antibody repertoire is sufficient to produce an antibody that is efficacious enough to be a good drug. Nevertheless, a further advantage is that human mAbs do not require humanization, a process that could be challenging and time consuming, and can result in antibodies with lowered affinities for their respective targets. Currently, two types of technologies are used to create human antibodies: transgenic mice and phage display of libraries of human antibodies [9].

After 20 years of effort, Karpas et al. in the University of Cambridge reported a human myeloma cell line (Karpas707H) that can give rise to stable human hybridomas capable of producing human monoclonal antibodies [23]. The cell line is useful for the generation of stable human hybridomas. It can easily be fused with ouabain-sensitive Epstein–Barr virus-transformed cells as well as with fresh tonsil and blood lymphocytes, giving rise to stable hybrids that continuously secrete very large quantities of human immunoglobulins. The derived hybrids do not lose immunoglobulin secretion over many months of continuous growth. The availability of this cell line should enable the in vitro immortalization of human antibody-producing B cells that are formed in vivo. The monoclonal antibodies produced may have advantages in immunotherapy. The cell line has the potential to immortalise most of the antibodies the human body produces to fight infections, cancer, acquired immunodeficiency syndrome (AIDS), and other pathological conditions [23]. Further molecular characterization study suggest that the hybridoma-derived antibodies are representative of antibodies from populations of human lymphocytes and at different stages in the maturation of the response; the use of Karpas707H myeloma for human hybridoma fusions may therefore provide a valuable tool for analysis of the human antibody responses [24]. Recently, Kametani et al. tried to prepare designed antigen-specific antibodies of completely human origin using immunodeficient mouse and human hybridoma [5]. Nonobese diabetic/severe combined immunodeficient/interleukin 2 (IL-2) receptor α null mouse (NOG) mouse was used to reconstitute the human immune system with umbilical cord blood hematopoietic stem cells (CB-NOG mouse) and to prepare human-derived Her-2-epitope-specific antibodies. Hybridoma lines were prepared by fusing the human myeloma cell line Karpas707H. Hybridoma lines were successfully prepared with spleen B cells obtained from the immunized CB-NOG mouse. One of these cell lines produced human IgM against the epitope peptide that can recognize the surface Her-2 molecule [25].

### 3.5 Transgenic Mice

XenoMouse or HuMouse are transgenic mice that have had their innate antibody genes replaced by human antibody genes, while leaving intact the other components of the mouse immune system [26–28]. As a result the transgenic mice produce human antibodies in response to immunization with an antigen. Once the mouse has been immunized, mAbs can either be generated through traditional hybridoma generation or by using genetic approaches to isolate B cells that produce the functional antibodies, followed by isolation of mAb genes and cloning into production cell lines. Within the field of transgenic mice, the two leading technology platforms are Medarex's HuMAb-Mouse and Abgenix's XenoMouse.

Medarex's UltiMAb platform uses transgenic mice, where mouse genes are suppressed and replaced with the expression of human antibody genes, to generate human antibodies. The technology platform includes three key antibody technologies; Medarex's HuMAb-Mouse technology; Kirin Brewery's TC Mouse technology; and the KM-Mouse technology, a crossbred mouse that has a combination of the characteristics of the HuMAb-Mouse and Kirin's TC Mouse technologies.

In the transgenic mice of the HuMAb-Mouse technology, mouse genes encoding antibodies have been inactivated and replaced with human antibody genes. These human genes encode unrearranged human antibody genes for both the heavy and light chains. Kirin's TC Mouse technology, on the other hand, has been developed so that the transgenic mice contain the complete set of variable and constant genes, which are found at the human immunoglobulin loci. In addition, the TC Mouse technology is capable of generating all antibody isotypes, as the mouse's chromosomes have been inactivated and replaced with human chromosomes that encode these. By combining the key features of these mice to create the KM-Mouse technology, Medarex and Kirin have generated a platform capable of making a broad range of antibodies because it has 100% of the human chromosomes for antibody genes. The ability to generate varied isotypes, in particular, allows a greater flexibility in designing therapeutic mAbs, as a particular isotype determines which effector functions of the immune response are induced.

Abgenix's XenoMouse and XenoMax are human antibody technologies using transgenic mice to create therapeutic monoclonal antibodies. Abgenix's XenoMouse is a transgenic mouse in which the mouse's antibody gene expression is suppressed and replaced with human antibody genes. However, the remainder of the mouse's immune system is left intact. The mice engineered through this process have approximately 80% of the human heavy-chain antibody genes as well as a significant amount of the light-chain genes. Abgenix has developed multiple strains of XenoMouse animals, each of which produces a different class of antibody to perform different therapeutic functions.

### 3.6 Phage Display

Phage display involves the engineering of bacteriophages to display human monoclonal antibodies on their surface [3, 28]. This is an important tool in studies aimed at identifying molecules, such as antibodies, that

bind to a specific target. Genes from extensive human antibody gene libraries are inserted into a population of phage. Each phage carries the genes for a different antibody and thus displays a different antibody on its surface. Antibodies are selected for binding to a target antigen, and the corresponding genes can be recovered and used in the development and potential manufacture of an antibody therapeutic product. The benefits of phage display are the huge size of the libraries. The larger the library, the more likely it is that an antibody can be isolated that binds effectively to the selected target. Certain libraries contain the genes for over 100 billion distinct antibodies. The recombination of the genes that code for the variable parts of an antibody allows further expansion of these libraries.

A number of companies are engaged in the development of human mAbs through phage display [29, 30] including Cambridge Antibody Technology (CAT) now part of AstraZenica, Dyax, and MorphoSys. CAT has created large libraries of billions of antibody genes collected from the blood of healthy individuals. CAT has used these gene libraries as the basis for the production of phage antibodies, created by phage display. By mixing the genes that code for the variable parts of an antibody (V genes) to give further combinations and inserting them into phage, CAT has created phage antibody libraries that now contain over 100 billion distinct phage antibodies. Six fully human therapeutic antibodies developed by CAT are at various stages of clinical trials, and Humira (adalimumab) was the first phage display antibody to reach the market, launched by Abbott in January 2003. Dyax's phage display libraries contain bacteriophages that display the Fab fragments of antibodies. Dyax developed its phage display libraries by taking gene fragments from human donors that encode the light-chain variable region and part of the heavy-chain variable region.

Advantages of phage display are the speed of identifying the initial antibody, which avoids the need for immunization in animals which usually takes several months [28]. However, the phage antibodies isolated in the first round of display are typically of very low affinity, and optimization (affinity maturation) of the antibody is necessary. Affinity maturation is the process by which B cells produce antibodies with increased affinity for antigen during the course of an immune response. With repeated exposures to the same antigen, a host will produce antibodies of successively greater affinities. A secondary response can elicit antibodies with several logfold greater affinities than in a primary response. Such affinity maturation process can be applied in test tubes by selecting a random mutated antibody population. Typically, in vitro affinity maturation takes a few months too.

Ribosome display involves the use of ribosomes to display functional antibody proteins in a test tube [29, 30]. Ribosome technology eliminates the need for phage particles and bacteria to generate antibodies and, therefore, represents a novel variation of phage display technology, with the potential to build even larger libraries. While the phage display technology is currently the more commercially important of the two technologies, ribosome display may be used as a supplement to phage display. Yeast display is a technique initially used in the field of protein engineering [31, 32]. A protein of interest is displayed as a fusion to the Aga2p protein on the surface of yeast. The Aga2p protein is naturally used by yeast to mediate cell–cell contacts during yeast cell mating. As such, display of a protein via Aga2p projects the protein away from the cell surface, minimizing potential interactions with other molecules on the yeast cell wall. The use of flow cytometry in conjunction with a yeast display library is a highly effective method to isolate high-affinity protein ligands (antigens) against nearly any receptor (antibodies) through directed evolution.

Advantages of yeast display over other in vitro evolution methods include eukaryotic expression and processing, quality control mechanisms of the eukaryotic secretory pathway, minimal avidity effects, and quantitative library screening through fluorescent-activated cell sorting (FACS). Disadvantages include smaller mutagenic library sizes compared to alternative methods and differential *glycosylation* in yeast compared to mammalian cells. It should be noted that these disadvantages have not limited the success of yeast display for a number of applications, including engineering the highest monovalent ligand-binding affinity reported to date for an engineered protein [33].

Mammalian cells such as Chinese hamster ovary cells are the dominant system used for the production of the majority of therapeutic antibodies in the pharmaceutical industry. Therefore, mammalian cells should be used in antibody selection to avoid problems caused by selection in microorganisms. A random peptide library fused to CCR5 and expressed on the mammalian cell surface has been reported [35]. The potential of this display system has been demonstrated for small peptides of 9 or 13 amino accids (aa). Ho et al. reported that human cells can be engineered for cell surface display of functional single-chain variable-fragment (scFv) antibodies and is suitable for affinity maturation. They used the anti-CD22 scFv fused to the transmembrane domain of human platelet-derived growth factor receptor (PDGFR) displayed on human embryonic kidney (HEK) 293T cells [34]. The mammalian cell scaffold allows hundredfold enrichment of a rare higher affinity mutant from a large excess of only slightly lower affinity initial antibody.

## 4 ANTIBODY ENGINEERING

### 4.1 Immunoconjugated Cancer Drugs

Monoclonal antibodies can be chemically conjugated to other molecules to create a different type of therapeutic agent. One way to achieve this is to use monoclonal antibodies as carriers of a small molecule or biologic drug to deliver drugs to a specific site, resulting in a localized and more direct action of the effector drug. This would limit the undesired effects on healthy cells that result from systemic treatment regimens, which is particularly problem with many cancer treatments available. At least three companies with key conjugation technology platforms: Seattle Genetics' antibody-drug conjugate (ADC) and antibody-directed enzyme prodrug therapy (ADEPT) technologies, ImmunoGen's tumor-activated prodrug technology, as well as Peregrine Pharmaceuticals' tumor necrosis therapy [36].

ImmunoGen's tumor-activated prodrug (TAP) technology is designed to conjugate a small-molecule prodrug to a given monoclonal antibody. In this situation the mAb acts as a carrier system, delivering the prodrug to specific cells by the recognition of a particular marker on cells. ImmunoGen's TAP technology creates a stable link between the mAb and the prodrug. The prodrug remains in its inactive state until it enters the specific cancer cell, when the link between the antibody and the prodrug is broken, releasing the prodrug. ImmunoGen is focused on using this technology to develop treatments for cancer, using mAbs that bind to specific markers associated with certain types of cancer.

Seattle Genetics has developed two conjugated antibody platforms: ADC and ADEPT technologies. The key components of the ADC technology are the stable, enzyme-cleavable linkers, such as hydrazones, and the highly potent, synthetic cytotoxic drugs. By using a rapidly internalizing mAb, the drug payload can be delivered inside target cells. The linkers are stable in the bloodstream, but the environment inside the target cell cleaves the linker, thereby releasing the drug payload. Until released, the drug is inactive, thereby sparing non-target cells many of the toxic effects of traditional chemotherapy. This is expected to translate into a more targeted, effective therapy and a better side effect profile for ADC products. The linkers used in ADC include an acid-labile hydrazone and protease-sensitive dipeptides such as valine-citrulline peptides. These have been shown in preclinical models to be much more stable in blood than conventional means of attaching drugs to mAbs. In vitro and in vivo testing has shown good stability of peptide-linked mAb conjugates with monomethylauristatin E, and good in vitro specificity and lower in vivo toxicity than corresponding hydrazone conjugates. These led to uniformly substituted conjugates that efficiently released active drug in the antigen-positive tumor cells. In vivo studies demonstrated that the peptide-linked conjugates induced regressions of established tumor xenografts with therapeutic indices (ratio of maximum tolerated dose to minimum curative dose) as high as 60-fold, indicating high tolerability. ADEPT on the other hand uses antibodies with tumor specificity that do not internalize but instead remain at the cell surface. These mAbs can be genetically engineered as fusion proteins with enzymes that then cleave nontoxic prodrugs and release chemotherapeutically active drugs at the tumor site. The ADEPT technology is a two-step process that combines two relatively nontoxic agents to achieve potent antitumor activity specifically within tumor tissue. In the first step, a tumor-targeting mAb is used to target catalytic enzymes to the surface of cancer cells. In the second step, inactive forms of anticancer drugs (prodrugs) are administered and converted to their fully active cytotoxic form by the enzyme that has been localized to the tumor microenvironment. This approach results in enzymatic conversion of prodrug to drug specifically in tumor tissue, thus reducing exposure of normal tissue to the drug while maximizing concentrations in tumor tissue [36].

There are currently four marketed conjugated antibody products, where the antibody acts as a carrier agent for the drug: Mylotarg (gemtuzumab ozogamicin), Biogen Idec/Schering AG's Zevalin (ibritumomab tiuxetan), Cotara and Bexxar (tositumomab-iodine 131), and a number of other such products in development. However, these marketed products have much lower sales compared with other antibody drugs. It is thought due to their limited efficacy and the complexity in administering such drugs, which require a radiologist and oncologist to oversee the administration, making them expensive and time-consuming treatment regimens [2]. Nonetheless, using monoclonal antibodies as carrier agents to deliver drugs to a specific site, resulting in a more direct action of the drug, has considerable therapeutic potential. This strategy can circumvent problems in treating complex diseases, such as cancer. Therapeutically effective conjugated antibodies should be eventually commercially viable and would have high potential for life-threatening conditions where there is high unmet need, such as cancer, despite their complex and expensive administration.

### 4.2 Fc Engineering

Scientists at Kyowa Hakko Kogyo Co. Ltd. (KHK) discovered that when an antibody had a reduced amount of fucose in its sugar chains, it exhibited much higher antigen-dependent cellular cytotoxicity (ADCC) activ-

ity as compared to a highly fucosylated conventional antibody. The elimination of fucose from sugar chains on an antibody has demonstrated enhanced therapeutic effects of monoclonal antibodies for cancer [37]. The ability to create fucose-free monoclonal antibodies allows enhancement of ADCC, the critical factor in anti-tumor activity. It was demonstrated that the mechanism behind the enhanced ADCC of a low/no-fucose antibody was its increased affinity to FcγRIIIa (CD16), the major Fc receptor for ADCC in humans. To take advantage of the above finding, scientists at Biowa Inc. knocked out a gene called *FUT*8 that is responsible for the fucose addition to sugar chains in order to create a new production method for fucose-free antibodies in Chinese hamster ovary (CHO) cells. The *FUT*8 knock-out CHO cells (Potelligent cells) produces fucose-free, thereby ADCC-enhanced antibodies (Potelligent maBs), with unchanged basic properties (stability, growth rate, productivity, and scalability) compared to parental CHO cells.

### 4.3 Bi-specific Antibodies

Two monoclonal antibodies can also be combined to create a bi-specific monoclonal antibody. These molecules are still at an early stage of development but have potential to harness the human immune system more effectively than single monoclonal antibodies because its mechanism of action is more alike to the natural immune system, which relies on polyclonal antibodies to generate an effective response. As a result, bi-specific molecules may be effective to treat more complex diseases [38, 39]. In a report Jimenez et al. constructed and produced a bispecific antibody, a diabody, using the variable domain genes of two neutralizing antibodies, *IMC-1121* to VEGFR2 and *hF4-3C5* to VEGFR3. The diabody binds to both VEGFR2 and VEGFR3 in a dose-dependent manner, and blocks interaction between VEGF/VEGFR2, VEGF-C/VEGFR2, and VEGF-C/VEGFR3. In cell-based assays, the diabody neutralized both VEGF and VEGF-C-stimulated activation of VEGFR2, VEGFR3, and p44/p42 mitogen-activated protein kinase in endothelial cells. Furthermore, the diabody was able to inhibit both vascular endothelial growth factor (VEGF) and VEGF-C-induced migration of endothelial cells. Taken together, these results suggest that a dual blockade of both VEGFR2 and VEGFR3 simultaneously may represent a more potent approach to effective cancer therapy [40].

### 4.4 Antibody Fragments

Antibody fragment is another key emerging area for mAbs therapeutic development. Fragments are small and, therefore, have a number of potential advantages over whole antibodies. The small size allows more extensive penetration of tissues such as solid tumors or eyes. Other advantages of antibody fragments are their lower cost of development and production often utilizing microbial expression systems. In addition it is possible to adjust the drug's half-life within the body.

The antigen-binding region of an antibody can be separated from the constant (Fc) portion to create a much smaller molecule (antigen-binding fragment or Fab) that contains the entire antigen-binding site and yet still binds specifically to its target. Removal of the Fc portion of an antibody may also decrease nonspecific binding between the Fc portion and Fc receptor bearing cells, which may increase specificity. Eliminating the Fc region can also lower immunogenicity, while maintaining specific antigenic properties. However, while this kind of microbial antibody fragment manufacturing system has some advantages, not all antibodies may be produced in this way. The fragments lack an Fc-binding region, which is responsible for certain functions such as ADCC. This makes fragments inappropriate for many antibody drug mechanisms, such as that used by Rituxan and Herceptin.

While fragments would generally be cleared more rapidly from the body than full antibodies, the half-life can be extended by modifications such as PEGylation. PEGylation is the process of attaching one or more chains of PEG to a protein molecule, which slow down the rapid clearance of the drug by the body. Current preclinical research is using multi-PEG technology, which allows numerous PEG molecules to be attached to Fab fragments, with the advantage of reduction in manufacturing costs through less wastage of PEG and a greater variability in half-life dependant on the size of the PEG fragments attached. The system for manufacturing Fab fragments in microbial systems allows fragments to be produced on a large scale at a lower cost.

Single-chain variable fragments are another category of antibody fragments that consist only of the variable heavy (VH) and variable light (VL) regions of a full antibody, connected by a synthetic peptide linker. Fab fragments differ from scFvs by containing not only the variable domains but also the constant regions of the light chain (Cl) and part of the heavy chain (Ch1), linked by a disulfide bridge. scFvs have similar binding properties but a smaller molecular size. Enzon Pharmaceuticals has developed the single-chain antibody (SCA) technology to develop drug candidates both independently and with partners. The most advanced SCA-based compound is pexelizumab, being developed by Enzon's licensee Alexion together with Procter & Gamble. Fabs are approximately one-third of the size of whole antibodies, while single-chain antibodies are about one-sixth of the size [41].

Domain Antibodies technology platform can be used to generate small fragments of antibodies, which correspond to the variable regions of either the (VH) or VL chains. The antibody fragments generated from this platform have a molecular weight of approximately 13 kDa, compared to a full antibody, which has a molecular weight of around 150 kDa. Domantis, acquired by GlaxoSmithKline, has created libraries that contain around 10 billion variants of fully human heavy and light chains and uses these libraries to select high-affinity antibody fragments for a given antigen [41]. Domain Antibodies technology has several key features compared with conventional antibodies [42]: The antibody fragments are well expressed in bacterial, yeast, and mammalian cells, which provides greater flexibility in manufacturing, including lower cost methods such as yeast and bacterial cells; the libraries are highly stable, and the antibody fragments can therefore withstand harsh treatment during testing and manufacturing; as the antibody fragments have low molecular weights compared to conventional antibodies, they can be manufactured at higher molar quantities per gram. Therefore, lower doses should be required compared with conventional antibodies, with lower costs per dose; domain antibodies can be delivered by injection and noninjectable routes, such as oral administration because the molecules are highly soluble and resistant to proteolysis during transit through the digestive system. In addition, the Domain Antibodies technology has the flexibility that two fragments can be combined to form a dimer, which can increase the specificity of the molecule binding to a specific antigen.

The commercial potential of antibody fragments is substantial, particularly in niche therapeutic areas that have not traditionally been targeted by antibody therapy. Genentech/Novartis's Lucentis (ranibizumab) for macular degeneration was put on the market recently. Two Fabs are in phase III development: CDP 870 (certolizumab pegol), UCB's antibody fragment for the treatment of rheumatoid arthritis; and Alexion/Procter & Gamble's pexelizumab for cardiopulmonary bypass graft surgery.

### 4.5 Fc-Based Protein Traps

Cytokines are among the best validated of the therapeutic targets. Cytokines can be blocked by the use of soluble receptors. Ebrel/etanercept is a soluable receptor that blocks TNF-α and is used for treating rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis. TNF-α promotes inflammation and its associated fever and signs (pain, tenderness, and swelling) in several inflammatory conditions, including rheumatoid arthritis and ankylosing spondylitis. Etanercept reduces the signs and symptoms of rheumatoid arthritis, the arthritis of psoriasis, and ankylosing spondylitis. It prevents the progressive destruction of the joints in patients with rheumatoid arthritis and the arthritis of psoriasis. A method called "cytokine traps" consisting of fusions between the constant region of IgG and the extracellular domains of two distinct cytokine receptors was developed by Economides et al. [43]. Traps potently block cytokines in vitro and in vivo and represent a substantial advance in creating novel therapeutic candidates for cytokine-driven diseases.

## 5 ANTIBODIES IN CLINICS

Monoclonal antibodies as therapies are better suited to certain therapy areas, such as immunodisorders and oncology, where they mimic the natural function of antibodies in the human immune system. The therapeutic application of monoclonal antibodies are mostly used the specificity of these molecules to block receptor–ligand interactions on cell surfaces or binding to receptors and modulating downstream biochemical pathways. However, the applicability of the antibody technologies is largely limited by the small number of disease targets where an extensive knowledge of extracellular receptor–ligand interaction is known to be involved in the pathogenicity of the disease. Despite the efforts in human genomics and protoemics, where numerous disease-related proteins are identified, most of the antibody targets are still limited to cytokines and growth factors and their respective receptors. For central nervous system (CNS) diseases, the concern is that antibodies cannot pass the blood–brain barrier. Nonetheless, respiratory and CNS are emerging as new therapy areas in the monoclonal antibody therapeutic areas. Genentech/Novartis's Xolair (omalizumab) was launched in 2003 by Genentech for the treatment of asthma. In addition, Biogen Idec and Elan launched Tysabri(natalizumab) in 2004 for multiple sclerosis. There are many diseases, beyond oncology and immunodisorders, where therapeutic antibodies can used to treat diseases. The high cost of therapeutic antibodies, however, restricts the commercial viability in those areas where small-molecule drugs are available to sufficiently treat the disease. Therefore, developing monoclonal antibodies targeting those diseases with high unmet need, where there is and will be a lack of competition from small molecules, have greater commercial viability.

Oncology and immunodisorders therapy areas are the therapeutic focus of the monoclonal antibody drug development industry because these molecules are well suited to treat such diseases. The oncology therapy area

is expected to grow significantly in the next 5–10 years. Much of the growth is forecast to be driven by the four best-selling oncology monoclonal antibodies in 2006, Rituxan, Herceptin, Avastin, and Erbitux. There are also a number of antibodies in development for oncology indications. The immunodisorders therapy is forecast to grow strongly over the next 5–10 years. The key growth drivers are expected to be three key rheumatoid arthritis and Crohn's disease antibody treatments: Remicade, Humira, and CDP 870. There is considerable room for further expansion of the immunodisoders product range beyond these markets and greater value can be extracted from monoclonal therapies. The third major focus is infectious disease, mainly attributed by Synagis and its follow-up product, Numax, pending FDA approval. Antibodies have the potential to treat many other infectious diseases, especially other viral infections, and thus there is considerable effort in R&D. Although a number of companies have begun developing antibodies for other viral infections, many of these are at early stages.

The monoclonal antibody is also encompassing a number of other therapy areas, including respiratory and ophthalmology, although at early stages. The therapeutic potential of antibodies outside of the oncology, immunodisorders, and infectious disease therapy areas, is limited due to their extracellular mechanism of action. Nonetheless, antibodies have the potential to treat some diseases that required intracellular activity, as by binding to external cell antigens, antibodies can interfere with downstream intracellular signaling pathways and thus convey a therapeutic benefit. However, extensive knowledge of a disease mechanism involving signaling pathways will be required to achieve this, which unfortunately still remains elusive for many diseases.

Since the mid-1990s, antibodies have emerged as an important new class of drug for therapeutic use across diverse clinical settings, including oncology, chronic inflammatory diseases, transplantation, infectious diseases, and cardiovascular medicine. The Food and Drug Administration (FDA) approved 23 antibody therapeutics, including 16 unmodified IgG molecules, 2 radioimmunoconjugates, 1 antibody–drug conjugate, 2 Fabs, and 2 Fc-fusion proteins, which comprise four different types: 3 murine, 5 chimeric, 11 humanized, and 2 human. At least 150 additional antibodies are in various stages of clinical development. One of the strengths of antibody therapeutics is that they belong to a well-established drug class that has a high success rate from the first use in humans to regulatory approval, the success rate amounting to 29% for chimeric antibodies and 25% for humanized antibodies. This compares favorably with the 11% success rate for small-molecule drugs. The global sale of monoclonal antibodies in 2006 were $21 billion. Remicade had annual sales $3.6 billion in 2006. Rituxan with 2006 sales of $4.7 billion was the best selling monoclonal antibody and biological product and the sixth among the top selling medicinal brands. Seven monoclonal antibody brands in 2006 had sales exceeding $1 billion. Humanized or fully human monoclonal antibodies with low immunogenicity, enhanced antigen binding, and reduced cellular toxicity provide better clinical efficacy. The higher technical and clinical success rate, overcoming of technical hurdles in large-scale manufacturing, low cost of market entry and investigational new drug (IND) filing, and use of fully human and humanized monoclonal antibodies have attracted funds and resources toward R&D. The antibody bandwagon has been joined by 200 companies with hundreds of new projects and targets and has attracted billions of dollars in R&D investment, acquisitions, and licensing deals leading to the current Monoclonal Antibody Gold Rush.

Tables 1 list all U.S. FDA-approved antibody drugs to date. Included in the table is the names of targets and antibodies, the names of products and companies, the source of the products, the approval date, and indications of the drugs. We now provide the detail description of each antibody drug.

**Orthoclone OKT3 (muromonab-CD3)** is a murine monoclonal antibody to the cell differentiation cluster 3 (CD3) antigen of human T cells that functions as an immunosuppressant [44]. The antibody is a biochemically purified IgG2a immunoglobulin with a heavy chain of approximately 50,000 Da and a light chain of approximately 25,000 Da. The proper name, muromonab-CD3, is derived from the descriptive term murine monoclonal antibody. The CD3 designation identifies the specificity of the antibody as the cell differentiation (CD) cluster 3 defined by the First International Workshop on Human Leukocyte Differentiation Antigens.

Orthoclone OKT3 reverses graft rejection, probably by blocking the function of T cells, which play a major role in acute allograft rejection. Orthoclone OKT3 reacts with and blocks the function of a 20,000-Da (CD3) in the membrane of human T cells that has been associated in vitro with the antigen recognition structure of T cells and is essential for signal transduction. In in vitro cytolytic assays, Orthoclone OKT3 blocks both the generation and function of effector cells. Binding of Orthoclone OKT3 to T lymphocytes results in early activation of T cells, which leads to cytokine release, followed by blocking T-cell functions. After termination of Orthoclone OKT3 therapy, T-cell function usually returns to normal within one week. In vivo, Orthoclone OKT3 reacts with most peripheral blood T cells and T cells in body tissues but has not been found to react with other hematopoietic elements or other tissues of the

body. A rapid and concomitant decrease in the number of circulating.

CD3 positive cells, including those that are CD2, CD4, or CD8 positive, has been observed in patients studied within minutes after the administration of Orthoclone OKT3. T-cell activation results in the release of numerous cytokines/lymphokines, which are felt to be responsible for many of the acute clinical manifestations seen following Orthoclone OKT3 administration. Orthoclone OKT3 is indicated for the treatment of acute allograft rejection in renal transplant patients. Orthoclone OKT3 is indicated for the treatment of steroid-resistant acute allograft rejection in cardiac and hepatic transplant patients.Orthoclone OKT3 should not be given to patients who are hypersensitive to products of murine origin, have uncontrolled hypertension, and have a history of seizures, or are predisposed to seizures.

**Abciximab, ReoPro**, is the Fab fragment of the chimeric human-murine monoclonal antibody 7E3 [45]. The chimeric 7E3 antibody is produced by continuous perfusion in mammalian cell culture. The 47,615-Da Fab fragment is purified from cell culture supernatant by a series of steps involving specific viral inactivation and removal procedures, digestion with papain, and column chromatography. Abciximab binds to the intact platelet GPIIb/IIIa receptor, which is a member of the integrin family of adhesion receptors and the major platelet surface receptor involved in platelet aggregation. Abciximab inhibits platelet aggregation by preventing the binding of fibrinogen, von Willebrand factor, and other adhesive molecules to GPIIb/IIIa receptor sites on activated platelets. The mechanism of action is thought to involve steric hindrance and/or conformational effects to block access of large molecules to the receptor rather than direct interaction with the RGD (arginine–glycine–aspartic acid) binding site of GPIIb/IIIa. Abciximab binds with similar affinity to the vitronectin receptor, also known as the avb3 integrin. The vitronectin receptor mediates the procoagulant properties of platelets and the proliferative properties of vascular endothelial and smooth muscle cells. Abciximab also binds to the activated Mac-1 receptor on monocytes and neutrophils. Abciximab is indicated as an adjunct to percutaneous coronary intervention for the prevention of cardiac ischemic complications in patients undergoing percutaneous coronary intervention and in patients with unstable angina not responding to conventional medical therapy when percutaneous coronary intervention is planned within 24 h. Safety and efficacy of abciximab use in patients not undergoing percutaneous coronary intervention have not been established. Abciximab is intended for use with aspirin and heparin and has been studied only in that setting. Because abciximab may increase the risk of bleeding, Abciximab is contraindicated in the following clinical situations: active internal bleeding; recent (within 6 weeks) gastrointestinal (GI) or genitourinary (GU) bleeding of clinical significance; history of cerebrovascular accident (CVA) within 2 years, or CVA with a significant residual neurological deficit; bleeding diathesis; administration of oral anticoagulants within 7 days unless prothrombin time is 1.2 times control; thrombocytopenia (<100,000 cells/μL); recent (within 6 weeks) major surgery or trauma; intracranial neoplasm, arteriovenous malformation, or aneurysm; severe uncontrolled hypertension; presumed or documented history of vasculitis; and use of intravenous dextran before percutaneous coronary intervention (PCI), or intent to use it during an intervention. Abciximab is also contraindicated in patients with known hypersensitivity to any component of this product or to murine proteins.

**Rituxan (rituximab)** is a genetically engineered chimeric murine/human monoclonal antibody directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes [46]. The antibody is an IgG1κ immunoglobulin containing murine light- and heavy-chain variable region sequences and human constant region sequences. Rituximab is composed of two heavy chains of 451 amino acids and two light chains of 213 amino acids and has an approximate molecular weight of 145 kDa. Rituximab has a binding affinity for the CD20 antigen of approximately 8.0 nM. The chimeric anti-CD20 antibody is produced by mammalian cell (CHO) suspension culture. The anti-CD20 antibody is purified by affinity and ion exchange chromatography. The purification process includes specific viral inactivation and removal procedures. Rituximab binds specifically to the antigen CD20 (human B-lymphocyte-restricted differentiation antigen, Bp35), a hydrophobic transmembrane protein with a molecular weight of approximately 35 kDa located on pre-B and mature B lymphocytes. The antigen is also expressed on >90% of B-cell non-Hodgkin's lymphomas (NHL) but is not found on hematopoietic stem cells, pro-B cells, normal plasma cells, or other normal tissues. CD20 regulates an early step(s) in the activation process for cell cycle initiation and differentiation and possibly functions as a calcium ion channel. B cells are believed to play a role in the pathogenesis of rheumatoid arthritis (RA) and associated chronic synovitis. In this setting, B cells may be acting at multiple sites in the autoimmune/inflammatory process, including through production of rheumatoid factor (RF) and other autoantibodies, antigen presentation, T-cell activation, and/or proinflammatory cytokine production. Rituxan (rituximab) is indicated for the treatment of patients with relapsed or refractory, low-grade or follicular, CD20-positive,

B-cell, non-Hodgkin's lymphoma; the first-line treatment of follicular, CD20-positive, B-cell non-Hodgkin's lymphoma in combination with CVP (cyclophosphamide + vincristine + prednisone) chemotherapy; the treatment of low-grade, CD20-positive, B-cell non-Hodgkin's lymphoma in patients with stable disease or who achieve a partial or complete response following first-line treatment with CVP chemotherapy; the first-line treatment of diffuse large B-cell, CD20-positive, non-Hodgkin's lymphoma in combination with CHOP (cyclophosphamide + hydroxydauno [doxorubicin] + Oncovin [vincristine] + prednisone) or other anthracycline-based chemotherapy regimens; in combination with methotrexate to reduce signs and symptoms in adult patients with moderately to severely active rheumatoid arthritis who have had an inadequate response to one or more TNF antagonist therapies. There is no contraindication for Rituxan.

**Zenapax (daclizumab)** is an immunosuppressive, humanized IgG1 monoclonal antibody produced by recombinant DNA technology that binds specifically to the α subunit (p55 α, CD25, or Tac subunit) of the human high-affinity IL-2 receptor that is expressed on the surface of activated lymphocytes [47]. Daclizumab is a composite of human (90%) and murine (10%) antibody sequences. The human sequences were derived from the constant domains of human IgG1 and the variable framework regions of the Eu myeloma antibody. The murine sequences were derived from the complementarity-determining regions of a murine anti-Tac antibody. The molecular weight predicted from the DNA sequence is 144 kDa.

Daclizumab functions as an IL-2 receptor antagonist that binds with high affinity to the Tac subunit of the high-affinity IL-2 receptor complex and inhibits IL-2 binding. Daclizumab binding is highly specific for Tac, which is expressed on activated but not resting lymphocytes. Administration of Zenapax inhibits IL-2-mediated activation of lymphocytes, a critical pathway in the cellular immune response involved in allograft rejection. Zenapax is indicated for the prophylaxis of acute organ rejection in patients receiving renal transplants. It is used as part of an immunosuppressive regimen that includes cyclosporine and corticosteroids. The efficacy of Zenapax for the prophylaxis of acute rejection in recipients of other solid organ allografts has not been demonstrated. Zenapax is contraindicated in patients with known hypersensitivity to daclizumab or to any components of this product.

**Simulect (basiliximab)** is a chimeric (murine–human) monoclonal antibody (IgG1-κ), produced by recombinant DNA technology, that functions as an immunosuppressive agent, specifically binding to and blocking the interleukin-2 receptor α chain (IL-2Rα, also known as CD25 antigen) on the surface of activated T lymphocytes [48]. Based on the amino acid sequence, the calculated molecular weight of the protein is 144 kDa. It is a glycoprotein obtained from fermentation of an established mouse myeloma cell line genetically engineered to express plasmids containing the human heavy- and light-chain constant region genes and mouse heavy- and light-chain variable region genes encoding the RFT5 antibody that binds selectively to the IL-2Rα.

Basiliximab functions as an IL-2 receptor antagonist by binding with high-affinity ($K_a = 1 \times 1010$ M-1) to the α chain of the high-affinity IL-2 receptor complex and inhibiting IL-2 binding. Basiliximab is specifically targeted against IL-2Rα, which is selectively expressed on the surface of activated T lymphocytes. This specific high-affinity binding of Simulect (basiliximab) to IL-2Rα competitively inhibits IL-2-mediated activation of lymphocytes, a critical pathway in the cellular immune response involved in allograft rejection. Simulect (basiliximab) is indicated for the prophylaxis of acute organ rejection in patients receiving renal transplantation when used as part of an immunosuppressive regimen that includes cyclosporine, United States Pharmacopeia (USP) (Modified), and corticosteroids. The efficacy of Simulect for the prophylaxis of acute rejection in recipients of other solid-organ allografts has not been demonstrated. Simulect (basiliximab) is contraindicated in patients with known hypersensitivity to basiliximab or any other component of the formulation.

**Synagis (palivizumab)** is a humanized monoclonal antibody (IgG1 produced by recombinant DNA technology), directed to an epitope in the A antigenic site of the F protein of respiratory syncytial virus (RSV) [49]. Synagis is a composite of human (95%) and murine (5%) antibody sequences. The human heavy-chain sequence was derived from the constant domains of human IgG1 and the variable framework regions of the VH genes *Cor* and *Cess*. The human light-chain sequence was derived from the constant domain of *C*κ and the variable framework regions of the VL gene *K104* with *J*κ-*4*. The murine sequences were derived from a murine monoclonal antibody, Mab 1129, in a process that involved the grafting of the murine complementarity determining regions into the human antibody frameworks. Synagis is composed of two heavy chains and two light chains and has a molecular weight of approximately 148,000 Da.

Synagis exhibits neutralizing and fusion-inhibitory activity against RSV. These activities inhibit RSV replication in laboratory experiments. Although resistant RSV strains may be isolated in laboratory studies, a panel of 57 clinical RSV isolates were all neutralized by

Synagis. The in vivo neutralizing activity of the active ingredient in Synagis was assessed in a randomized, placebo-controlled study of 35 pediatric patients tracheally intubated because of RSV disease. In these patients, Synagis significantly reduced the quantity of RSV in the lower respiratory tract compared to control patients. Synagis is indicated for the prevention of serious lower respiratory tract disease caused by RSV in pediatric patients at high risk of RSV disease. Safety and efficacy were established in infants with bronchopulmonary dysplasia (BPD), infants with a history of premature birth (≤35 weeks gestational age), and children with hemodynamically significant congenital heart disease (CHD). Synagis should not be used in pediatric patients with a history of a severe prior reaction to Synagis or other components of this product.

**Remicade** is a chimeric IgG1-κ monoclonal antibody with an approximate molecular weight of 149,100 Da [50]. It is composed of human constant and murine variable regions. Infliximab binds specifically to human TNF-α with an association constant of 1010 $M^{-1}$. Infliximab is produced by a recombinant cell line cultured by continuous perfusion and is purified by a series of steps that includes measures to inactivate and remove viruses.

Infliximab neutralizes the biological activity of TNF-α by binding with high affinity to the soluble and transmembrane forms of TNF-α and inhibits binding of TNF-α with its receptors. Infliximab does not neutralize TNF-β (lymphotoxin α), a related cytokine that utilizes the same receptors as TNF-α. Biological activities attributed to TNF-α include induction of proinflammatory cytokines such as interleukins (IL) 1 and 6, enhancement of leukocyte migration by increasing endothelial layer permeability and expression of adhesion molecules by endothelial cells and leukocytes, activation of neutrophil and eosinophil functional activity, induction of acute-phase reactants and other liver proteins, as well as tissue-degrading enzymes produced by synoviocytes and/or chondrocytes. Cells expressing transmembrane TNF-α bound by infliximab can be lysed in vitro or in vivo. Infliximab inhibits the functional activity of TNF-α in a wide variety of in vitro bioassays utilizing human fibroblasts, endothelial cells, neutrophils, B and T lymphocytes, and epithelial cells. The relationship of these biological response markers to the mechanism(s) by which Remicade exerts its clinical effects is unknown. Anti-TNF-α antibodies reduce disease activity in the model of collagen-induced arthritis. Infliximab prevents disease in transgenic mice that develop polyarthritis as a result of constitutive expression of human TNF-α, and when administered after disease onset, allows eroded joints to heal.

Remicade, in combination with methotrexate, is indicated for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis.

Remicade is indicated for reducing signs and symptoms and inducing and maintaining clinical remission in adult and pediatric patients with moderately to severely active Crohn's disease who have had an inadequate response to conventional therapy.

Remicade is indicated for reducing the number of draining enterocutaneous and rectovaginal fistulas and maintaining fistula closure in adult patients with fistulizing Crohn's disease.

Remicade is indicated for reducing signs and symptoms in patients with active ankylosing spondylitis.

Remicade is indicated for reducing signs and symptoms of active arthritis, inhibiting the progression of structural damage, and improving physical function in patients with psoriatic arthritis.

Remicade is indicated for the treatment of adult patients with chronic severe (i.e., extensive and /or disabling) plaque psoriasis who are candidates for systemic therapy and when other systemic therapies are medically less appropriate. Remicade should only be administered to patients who will be closely monitored and have regular follow-up visits with a physician.

Remicade is indicated for reducing signs and symptoms, inducing and maintaining clinical remission and mucosal healing, and eliminating corticosteroid use in patients with moderately to severely active ulcerative colitis who have had an inadequate response to conventional therapy.

Remicade at doses >5 mg/kg should not be administered to patients with moderate to severe heart failure. In a randomized study evaluating Remicade in patients with moderate to severe heart failure [New York Heart Association (NYHA) Functional Class III/IV], Remicade treatment at 10 mg/kg was associated with an increased incidence of death and hospitalization due to worsening heart failure.

Remicade should not be readministered to patients who have experienced a severe hypersensitivity reaction to Remicade.

Additionally, Remicade should not be administered to patients with known hypersensitivity to inactive components of the product or to any murine proteins.

**Herceptin (trastuzumab)** is a recombinant DNA-derived humanized monoclonal antibody that selectively binds with high affinity in a cell-based assay ($K_d = 5\,nM$) to the extracellular domain of the human epidermal growth factor receptor 2 protein, HER2 [51]. The antibody is an IgG1κ that contains human frame-

work regions with the complementarity-determining regions of a murine antibody (4D5) that binds to HER2. The humanized antibody against HER2 is produced by a mammalian cell (CHO) suspension culture. The HER2 (or c-erbB2) proto-oncogene encodes a transmembrane receptor protein of 185 kDa, which is structurally related to the epidermal growth factor receptor. HER2 protein overexpression is observed in 25–30% of primary breast cancers. HER2 protein overexpression can be determined using immunohistochemistry (IHC). The presence of HER2 overexpression may also be inferred when HER2 gene amplification is identified using fluorescence in situ hybridization (FISH) on fixed tumor blocks. Trastuzumab has been shown, in both in vitro assays and in animals, to inhibit the proliferation of human tumor cells that overexpress HER2. Trastuzumab is a mediator of ADCC. In vitro, Herceptin-mediated ADCC has been shown to be preferentially exerted on HER2 overexpressing cancer cells compared with cancer cells that do not overexpress HER2. Herceptin (trastuzumab), as part of a treatment regimen containing doxorubicin, cyclophosphamide, and paclitaxel, is indicated for the adjuvant treatment of patients with HER2-overexpressing, node-positive breast cancer. Herceptin as a single agent is indicated for the treatment of patients with metastatic breast cancer whose tumors overexpress the HER2 protein and who have received one or more chemotherapy regimens for their metastatic disease. Herceptin in combination with paclitaxel is indicated for treatment of patients with metastatic breast cancer whose tumors overexpress the HER2 protein and who have not received chemotherapy for their metastatic disease. There is no contraindication for Herceptin.

**Enbrel (etanercept)** is a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human 75-kDa (p75) tumor necrosis factor receptor (TNFR) linked to the Fc portion of human IgG1 [52]. The Fc component of etanercept contains the CH2 domain, the CH3 domain and hinge region, but not the CH1 domain of IgG1. Etanercept is produced by recombinant DNA technology in a CHO mammalian cell expression system. It consists of 934 amino acids and has an apparent molecular weight of approximately 150 kDa. Etanercept binds specifically to TNF and blocks its interaction with cell surface TNF receptors. TNF is a naturally occurring cytokine that is involved in normal inflammatory and immune responses. It plays an important role in the inflammatory processes of RA, polyarticular-course juvenile rheumatoid arthritis (JRA), and ankylosing spondylitis (AS) and the resulting joint pathology. In addition, TNF plays a role in the inflammatory process of plaque psoriasis. Elevated levels of TNF are found in involved tissues and fluids of patients with RA, psoriatic arthritis, AS, and plaque psoriasis. Two distinct receptors for TNF (TNFRs), a 55-kDa protein (p55) and a 75-kDa protein (p75), exist naturally as monomeric molecules on cell surfaces and in soluble forms. Biological activity of TNF is dependent upon binding to either cell surface TNFR. Etanercept is a dimeric soluble form of the p75 TNF receptor that can bind to two TNF molecules. It inhibits the activity of TNF in vitro and has been shown to affect several animal models of inflammation, including murine collagen-induced arthritis. Etanercept inhibits binding of both TNFa and TNFb [lymphotoxin alpha [LTa]] to cell surface TNFRs, rendering TNF biologically inactive. Cells expressing transmembrane TNF that bind Enbrel are not lysed in vitro in the presence or absence of complement. Etanercept can also modulate biological responses that are induced or regulated by TNF, including expression of adhesion molecules responsible for leukocyte migration (i.e., E-selectin and to a lesser extent intercellular adhesion molecule-1 [ICAM-1]), serum levels of cytokines (e.g., IL-6), and serum levels of matrix metalloproteinase-3 (MMP-3 or stromelysin). Enbrel is indicated for reducing signs and symptoms, inducing major clinical response, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis. Enbrel can be initiated in combination with methotrexate (MTX) or used alone. Enbrel is indicated for reducing signs and symptoms of moderately to severely active polyarticular-course IRA in patients who have had an inadequate response to one or more disease-modifying antirheumatic drugs (DMARDs). Enbrel is indicated for reducing signs and symptoms, inhibiting the progression of structural damage of active arthritis, and improving physical function in patients with psoriatic arthritis. Enbrel can be used in combination with methotrexate in patients who do not respond adequately to methotrexate alone. Enbrel is indicated for reducing signs and symptoms in patients with active ankylosing spondylitis. Enbrel is indicated for the treatment of adult patients (18 years or older) with chronic moderate to severe plaque psoriasis who are candidates for systemic therapy or phototherapy. Enbrel should not be administered to patients with sepsis or with known hypersensitivity to ENBREL or any of its components.

**Mylotarg (gemtuzumab ozogamicin)** is a chemotherapy agent composed of a recombinant humanized IgG4κ, antibody conjugated with a cytotoxic antitumor antibiotic, calicheamicin, isolated from fermentation of a bacterium, *Micromonospora echinospora* sp. *Calichensis* [53]. The antibody portion of Mylotarg binds

specifically to the CD33 antigen, a sialic-acid-dependent adhesion protein found on the surface of leukemic myeloblasts and immature normal cells of myelomonocytic lineage, but not on normal hematopoetic stem cells. The anti-CD33 hP67.6 antibody is produced by mammalian cell suspension culture using a myeloma NS0 cell line and is purified under conditions that remove or inactivate viruses. Mylotarg contains amino acid sequences of which approximately 98.3% are of human origin. The constant region and framework regions contain human sequences while the CDRs are derived from a murine antibody (p67.6) that binds CD33. This antibody is linked to *N*-acetyl-γ-calicheamicin via a bifunctional linker. Gemtuzumab ozogamicin has approximately 50% of the antibody loaded with 4–6 mol calicheamicin per mole of antibody. The remaining 50% of the antibody is not linked to the calicheamicin derivative. Gemtuzumab ozogamicin has a molecular weight of 151–153,000 Da. Gemtuzumab ozogamicin binds to the CD33 antigen. This antigen is expressed on the surface of leukemic blasts in more than 80% of patients with acute myeloid leukemia (AML). CD33 is also expressed on normal and leukemic myeloid colony-forming cells, including leukemic clonogenic precursors, but it is not expressed on pluripotent hematopoietic stem cells or on nonhematopoietic cells. Binding of the anti-CD33 antibody portion of Mylotarg with the CD33 antigen results in the formation of a complex that is internalized. Upon internalization, the calicheamicin derivative is released inside the lysosomes of the myeloid cell. The released calicheamicin derivative binds to DNA in the minor groove resulting in DNA double-strand breaks and cell death. Gemtuzumab ozogamicin is cytotoxic to the CD33-positive HL-60 human leukemia cell line. Gemtuzumab ozogamicin produces significant inhibition of colony formation in cultures of adult leukemic bone marrow cells. The cytotoxic effect on normal myeloid precursors leads to substantial myelosuppression, but this is reversible because pluripotent hematopoietic stem cells are spared. In preclinical animal studies, gemtuzumab ozogamicin demonstrates antitumor effects in the HL-60 human promyelocytic leukemia xenograft tumor in athymic mice. Mylotarg is indicated for the treatment of patients with CD33-positive AML in first relapse who are 60 years of age or older and who are not considered candidates for cytotoxic chemotherapy. The safety and efficacy of Mylotarg in patients with poor performance status and organ dysfunction has not been established. There are no controlled trials demonstrating a clinical benefit, such as improvement in disease-related symptoms or increased survival, compared to any other treatment. Mylotarg is contraindicated in patients with a known hypersensitivity to gemtuzumab ozogamicin or any of its components: anti-CD33 antibody (hP67.6), calicheamicin derivatives, or inactive ingredients.

**Campath (alemtuzumab)** is a recombinant DNA-derived humanized monoclonal antibody (Campath-1H) that is directed against the 21- to 28-kD cell surface glycoprotein, CD52 [54]. The Campath-1H antibody is an IgG1κ with human variable framework and constant regions, and CDRs from a murine (rat) monoclonal antibody (Campath-1G). The Campath-1H antibody has an approximate molecular weight of 150 kDa. Campath is produced in mammalian cell (CHO) suspension culture. Alemtuzumab binds to CD52, a non-modulating antigen that is present on the surface of essentially all B and T lymphocytes, a majority of monocytes, macrophages, and natural killer (NK) cells, and a subpopulation of granulocytes. Analysis of samples collected from multiple volunteers has not identified CD52 expression on erythrocytes or hematopoetic stem cells. The proposed mechanism of action is anti-body-dependent lysis of leukemic cells following cell surface binding. Campath-1H Fab binding was observed in lymphoid tissues and the mononuclear phagocyte system. A proportion of bone marrow cells, including some CD34+ cells, express variable levels of CD52. Significant binding was also observed in the skin and male reproductive tract (epididymis, sperm, seminal vesicle). Mature spermatozoa stain for CD52, but neither spermatogenic cells nor immature spermatozoa show evidence of staining. Campath is indicated for the treatment of B-cell chronic lymphocytic leukemia (B-CLL) in patients who have been treated with alkylating agents and who have failed fludarabine therapy. Determination of the effectiveness of Campath is based on overall response rates. Comparative, randomized trials demonstrating increased survival or clinical benefits such as improvement in disease-related symptoms have not yet been conducted.

Campath is contraindicated in patients who have active systemic infections, underlying immunodeficiency [e.g., seropositive for (human immunodeficiency virus (HIV)], or known type I hypersensitivity or anaphylactic reactions to Campath or to any one of its components.

**Zevalin (ibritumomab tiuxetan)** is the immunoconjugate resulting from a stable thiourea covalent bond between the monoclonal antibody ibritumomab and the linker-chelator tiuxetan [*N*-[2-bis(carboxymethyl) amino]-3-(p-isothiocyanatophenyl)-propyl]-[*N*-[2-bis(carboxymethyl)amino]-2-(methyl)-ethyl]glycine [54]. This linker-chelator provides a high affinity, conformationally restricted chelation site for indium-111 or yttrium-90. The approximate molecular weight of ibri-

tumomab tiuxetan is 148 kDa. The antibody moiety of Zevalin is ibritumomab, a murine IgG1κ monoclonal antibody directed against the CD20 antigen, which is found on the surface of normal and malignant B lymphocytes. Ibritumomab is produced in CHO cells and is composed of two murine γ 1 heavy chains of 445 amino acids each and two κ light chains of 213 amino acids each.

Ibritumomab tiuxetan binds specifically to the CD20 antigen (human B-lymphocyte-restricted differentiation antigen, Bp35). The apparent affinity ($K_d$) of ibritumomab tiuxetan for the CD20 antigen ranges between approximately 14 on 18 n*M*. The CD20 antigen is expressed on pre-B and mature-B lymphocytes and on >90% of B-cell NHL. The CD20 antigen is not shed from the cell surface and does not internalize upon antibody binding.

*Mechanism of Action*: The complementarity-determining regions of ibritumomab bind to the CD20 antigen on B lymphocytes. Ibritumomab, like rituximab, induces apoptosis in CD20+ B-cell lines in vitro. The chelate tiuxetan, which tightly binds In-111 or Y-90, is covalently linked to the amino groups of exposed lysines and arginines contained within the antibody. The β emission from Y-90 induces cellular damage by the formation of free radicals in the target and neighboring cells. Zevalin, as part of the Zevalin therapeutic regimen, is indicated for the treatment of patients with relapsed or refractory low-grade, follicular, or transformed B-cell non-Hodgkin's lymphoma, including patients with rituximab refractory follicular non-Hodgkin's lymphoma. Determination of the effectiveness of the Zevalin therapeutic regimen in a relapsed or refractory patient population is based on overall response rates. The effects of the Zevalin therapeutic regimen on survival are not known. The Zevalin therapeutic regimen is contraindicated in known type I hypersensitivity or anaphylactic reaction proteins or to any component of this product, including yttrium chloride and indium chloride.

**Humira (adalimumab)** is a recombinant human IgG1 monoclonal antibody specific for human tumor necrosis factor [55]. Humira was created using phage display technology resulting in an antibody with human-derived heavy- and light-chain variable regions and human IgG1κ constant regions. Adalimumab is produced by recombinant DNA technology in a mammalian cell expression system and is purified by a process that includes specific viral inactivation and removal steps. It consists of 1330 amino acids and has a molecular weight of approximately 148 kDa. Adalimumab binds specifically to TNF-α and blocks its interaction with the p55 and p75 cell surface TNF receptors. Adalimumab also lyses surface TNF expressing cells in vitro in the presence of complement. Adalimumab does not bind or inactivate lymphotoxin (TNF-β). TNF is a naturally occurring cytokine that is involved in normal inflammatory and immune responses. Elevated levels of TNF are found in the synovial fluid of rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis patients and play an important role in both the pathologic inflammation and the joint destruction that are hallmarks of these diseases. Adalimumab also modulates biological responses that are induced or regulated by TNF, including changes in the levels of adhesion molecules responsible for leukocyte migration (ELAM-1 [endothelial-leukocyte adhesion molecule 1], VCAM-1 [vascular-cell adhesion molecule 1], and ICAM-1 [intercellular-adhesion molecule 1] with an $IC_{50}$ of $1–2 \times 10^{-10} M$). Humira is a TNF blocker indicated for treatment of RA: Reducing signs and symptoms, inducing major clinical response, inhibiting the progression of structural damage, and improving physical function in adult patients with moderately to severely active disease. For the treatment of psoriatic arthritis: Reducing signs and symptoms of active arthritis, inhibiting the progression of structural damage, and improving physical function. For the treatment of ankylosing spondylitis: reducing signs and symptoms in patients with active disease. For treatment of Crohn's disease: reducing signs and symptoms and inducing and maintaining clinical remission in adult patients with moderately to severely active Crohn's disease who have had an inadequate response to conventional therapy. Reducing signs and symptoms and inducing clinical remission in these patients if they have also lost response to or are intolerant of infliximab. There are no contraindications for Humira.

**Xolair (omalizumab)** is a recombinant DNA-derived humanized IgG1κ monoclonal antibody that selectively binds to human immunoglobulin E (IgE). The antibody has a molecular weight of approximately 149,000 Da. Xolair is produced by a CHO cell suspension culture [56]. Xolair inhibits the binding of IgE to the high-affinity IgE receptor (FcεRI) on the surface of mast cells and basophils. Reduction in surface-bound IgE on FcεRI-bearing cells limits the degree of release of mediators of the allergic response. Treatment with Xolair also reduces the number of FcεRI receptors on basophils in atopic patients. A variety of studies have found that omalizumab decreases inflammatory mediators. The result of blocking the IgE high-affinity Fc receptor is manifolds. Omalizumab treatment downregulates dendritic cell FcεRI expression. The combined effect of specific immunotherapy (SIT) and omalizumab is associated with prevention of nasal eosinophilic cationic protein increase and decreased tryptase levels in nasal

secretions. Anti-IgE therapy reduces leukotriene release of peripheral leukocytes stimulated with allergen in children with allergic rhinitis undergoing allergen immunotherapy independent of the type of SIT allergen used. Xolair (omalizumab) is indicated for adults and adolescents (12 years of age and above) with moderate to severe persistent asthma who have a positive skin test or in vitro reactivity to a perennial aeroallergen and whose symptoms are inadequately controlled with inhaled corticosteroids. Xolair has been shown to decrease the incidence of asthma exacerbations in these patients. Safety and efficacy have not been established in other allergic conditions. Xolair should not be administered to patients who have experienced a severe hypersensitivity reaction to Xolair.

**Bexxar (tositumomab and iodine $^{131}$I tositumomab)** is an antineoplastic radioimmunotherapeutic mAb-based regimen composed of the monoclonal antibody tositumomab and the radiolabeled monoclonal antibody iodine $^{131}$I tositumomab [57, 58]. Tositumomab is a murine IgG2aλ monoclonal antibody directed against the CD20 antigen, which is found on the surface of normal and malignant B lymphocytes. Tositumomab is produced in an antibiotic-free culture of mammalian cells and is composed of two murine γ2a heavy chains of 451 amino acids each and two λ light chains of 220 amino acids each. The approximate molecular weight of tositumomab is 150,000 Da. Iodine $^{131}$I tositumomab is a radio-iodinated derivative of tositumomab that has been covalently linked to $^{131}$iodine. Tositumomab binds specifically to the CD20 (human B-lymphocyte-restricted differentiation antigen, Bp 35 or B1) antigen. This antigen is a transmembrane phosphoprotein expressed on pre-B lymphocytes and at higher density on mature-B lymphocytes. The antigen is also expressed on >90% of B-cell NHL. The recognition epitope for tositumomab is found within the extracellular domain of the CD20 antigen. CD20 does not shed from the cell surface and does not internalize following antibody binding. Possible mechanisms of action of the Bexxar therapeutic regimen include induction of apoptosis, complement-dependent cytotoxicity (CDC) and ADCC mediated by the antibody. Additionally, cell death is associated with ionizing radiation from the radioisotope. The Bexxar therapeutic regimen (tositumomab and iodine $^{131}$I tositumomab) is indicated for the treatment of patients with CD20 antigen-expressing relapsed or refractory, low-grade, follicular, or transformed NHL, including patients with rituximab-refractory NHL. Determination of the effectiveness of the Bexxar therapeutic regimen is based on overall response rates in patients whose disease is refractory to chemotherapy alone or to chemotherapy and rituximab. The effects of the Bexxar therapeutic regimen on survival are not known. The Bexxar therapeutic regimen is not indicated for the initial treatment of patients with CD20-positive NHL. The Bexxar therapeutic regimen is intended as a single course of treatment. The safety of multiple courses of the Bexxar therapeutic regimen, or combination of this regimen with other forms of irradiation or chemotherapy, has not been evaluated. The Bexxar therapeutic regimen is contraindicated in patients with known hypersensitivity to murine proteins or any other component of the Bexxar therapeutic regimen.

**Raptiva (efalizumab)** is an immunosuppressive recombinant humanized IgG1κ isotype monoclonal antibody that binds to human CD11a [59]. Efalizumab has a molecular weight of approximately 150,000 Da and is produced in a CHO mammalian cell expression system. Raptiva binds to CD11a, a subunit of leukocyte function antigen-1 (LFA-1), which is expressed on all leukocytes, and decreases cell surface expression of CD11a. Raptiva inhibits the binding of LFA-1 to intercellular adhesion molecule-1 (ICAM-1), thereby inhibiting the adhesion of leukocytes to other cell types. Interaction between LFA-1 and ICAM-1 contributes to the initiation and maintenance of multiple processes, including activation of T lymphocytes, adhesion of T lymphocytes to endothelial cells, and migration of T lymphocytes to sites of inflammation including psoriatic skin. Lymphocyte activation and trafficking to skin play a role in the pathophysiology of chronic plaque psoriasis. In psoriatic skin, ICAM-1 cell surface expression is upregulated on endothelium and keratinocytes. CD11a is also expressed on the surface of B lymphocytes, monocytes, neutrophils, NK cells, and other leukocytes. Therefore, the potential exists for Raptiva to affect the activation, adhesion, migration, and numbers of cells other than T lymphocytes. Raptiva (efalizumab) is indicated for the treatment of adult patients (18 years or older) with chronic moderate to severe plaque psoriasis who are candidates for systemic therapy or phototherapy. Raptiva should not be administered to patients with known hypersensitivity to Raptiva or any of its components.

**Amevive (alefacept)** is an immunosuppressive dimeric fusion protein that consists of the extracellular CD2-binding portion of the human LFA-3 linked to the Fc (hinge, CH2, and CH3 domains) portion of human IgG1 [60]. Alefacept is produced by recombinant DNA technology in a CHO mammalian cell expression system. The molecular weight of alefacept is 91,400 Da. Amevive interferes with lymphocyte activation by specifically binding to the lymphocyte antigen, CD2, and inhibiting LFA-3/CD2 interaction. Activation of T lym-

phocytes involving the interaction between LFA-3 on antigen-presenting cells and CD2 on T lymphocytes plays a role in the pathophysiology of chronic plaque psoriasis. The majority of T lymphocytes in psoriatic lesions are of the memory effector phenotype characterized by the presence of the CD45RO marker1, express activation markers (e.g., CD25, CD69) and release inflammatory cytokines, such as interferon γ.

Amevive also causes a reduction in subsets of CD2+ T lymphocytes (primarily CD45RO+), presumably by bridging between CD2 on target lymphocytes and immunoglobulin Fc receptors on cytotoxic cells, such as NK cells. Treatment with Amevive results in a reduction in circulating total CD4+ and CD8+ T-lymphocyte counts. CD2 is also expressed at low levels on the surface of NK cells and certain bone marrow B lymphocytes. Therefore, the potential exists for Amevive to affect the activation and numbers of cells other than T lymphocytes. In clinical studies of Amevive, minor changes in the numbers of circulating cells other than T lymphocytes have been observed. Amevive is indicated for the treatment of adult patients with moderate to severe chronic plaque psoriasis who are candidates for systemic therapy or phototherapy. Amevive should not be administered to patients infected with HIV. Amevive reduces CD4+ T-lymphocyte counts, which might accelerate disease progression or increase complications of disease in these patients. Amevive should not be administered to patients with known hypersensitivity to Amevive or any of its components.

**Erbitux (cetuximab)** is a recombinant, human/mouse chimeric monoclonal antibody that binds specifically to the extracellular domain of the human epidermal growth factor receptor (EGFR) [61]. Cetuximab is composed of the Fv regions of a murine anti-EGFR antibody with human IgG1 heavy- and κ light-chain constant regions and has an approximate molecular weight of 152 kDa. Cetuximab is produced in mammalian (murine myeloma) cell culture. The epidermal growth factor receptor (EGFR, HER1, c-ErbB-1) is a transmembrane glycoprotein that is a member of a subfamily of type I receptor tyrosine kinases including EGFR, HER2, HER3, and HER4. The EGFR is constitutively expressed in many normal epithelial tissues, including the skin and hair follicle. Expression of EGFR is also detected in many human cancers, including those of the head and neck, colon, and rectum. Cetuximab binds specifically to the EGFR on both normal and tumor cells, and competitively inhibits the binding of epidermal growth factor (EGF) and other ligands, such as transforming growth factor-α. In vitro assays and in vivo animal studies have shown that binding of cetuximab to the EGFR blocks phosphorylation and activation of receptor-associated kinases, resulting in inhibition of cell growth, induction of apoptosis, and decreased matrix metalloproteinase and vascular endothelial growth factor production. In vitro, cetuximab can mediate ADCC against certain human tumor types. While the mechanism of cetuximab's antitumor effect(s) in vivo is unknown, all of these processes may contribute to the overall therapeutic effect of cetuximab. In vitro assays and in vivo animal studies have shown that cetuximab inhibits the growth and survival of tumor cells that express the EGFR. No antitumor effects of cetuximab were observed in human tumor xenografts lacking EGFR expression. The addition of cetuximab to radiation therapy, irinotecan, or irinotecan plus 5-fluorouracil in human tumor xenograft models in mice resulted in an increase in antitumor effects compared to radiation therapy or chemotherapy alone. Erbitux (cetuximab), in combination with radiation therapy, is indicated for the treatment of locally or regionally advanced squamous cell carcinoma of the head and neck. Erbitux as a single agent is indicated for the treatment of patients with recurrent or metastatic squamous cell carcinoma of the head and neck for whom prior platinum-based therapy has failed.

Erbitux, used in combination with irinotecan, is indicated for the treatment of EGFR-expressing, metastatic colorectal carcinoma in patients who are refractory to irinotecan-based chemotherapy. Erbitux administered as a single agent is indicated for the treatment of EGFR-expressing, metastatic colorectal carcinoma in patients who are intolerant of irinotecan-based chemotherapy. The effectiveness of Erbitux for the treatment of EGFR-expressing, metastatic colorectal carcinoma is based on objective response rates. Currently, no data are available that demonstrate an improvement in disease-related symptoms or increased survival with Erbitux for the treatment of EGFR-expressing, metastatic colorectal carcinoma. There are no contraindications for Erbitux.

**Avastin (bevacizumab)** is a recombinant humanized monoclonal IgG1 antibody that binds to and inhibits the biologic activity of human VEGF in in vitro and in vivo assay systems [62]. Bevacizumab contains human framework regions and the complementarity-determining regions of a murine antibody that binds to VEGF. Bevacizumab is produced in a CHO mammalian cell expression system and has a molecular weight of approximately 149,000 Da. Bevacizumab binds VEGF and prevents the interaction of VEGF to its receptors (Flt-1 and KDR) on the surface of endothelial cells. The interaction of VEGF with its receptors leads to endothelial cell proliferation and new blood vessel formation in in vitro models of angiogenesis. Administration of

bevacizumab to xenotransplant models of colon cancer in nude (athymic) mice caused reduction of microvascular growth and inhibition of metastatic disease progression. Avastin, in combination with intravenous 5-fluorouracil-based chemotherapy, is indicated for first- or second-line treatment of patients with metastatic carcinoma of the colon or rectum. Avastin, in combination with carboplatin and paclitaxel, is indicated for first-line treatment of patients with unresectable, locally advanced, recurrent or metastatic nonsquamous, non-small-cell lung cancer. There are no contraindications for Avastin.

**Tysabri (natalizumab)** is a recombinant humanized IgG4κ monoclonal antibody produced in murine myeloma cells [63]. Natalizumab contains human framework regions and the complementarity-determining regions of a murine antibody that binds to α4-integrin. The molecular weight of natalizumab is 149,000 Da. Tysabri binds to the α4 subunit of α4β1 and α4β7 integrins expressed on the surface of all leukocytes except neutrophils, and inhibits the α4-mediated adhesion of leukocytes to their counterreceptor(s). The receptors for the α4 family of integrins include vascular cell adhesion molecule-1 (VCAM-1), which is expressed on activated vascular endothelium, and mucosal address in cell adhesion molecule-1 (MadCAM-1) present on vascular endothelial cells of the gastrointestinal tract. Disruption of these molecular interactions prevents transmigration of leukocytes across the endothelium into inflamed parenchymal tissue. In vitro, anti-α4-integrin antibodies also block α4-mediated cell binding to ligands such as osteopontin and an alternatively spliced domain of fibronectin, connecting segment-1 (CS-1). In vivo, Tysabri may further act to inhibit the interaction of α4-expressing leukocytes with their ligand(s) in the extracellular matrix and on parenchymal cells, thereby inhibiting further recruitment and inflammatory activity of activated immune cells. The specific mechanism(s) by which Tysabri exerts its effects in multiple sclerosis have not been fully defined. In multiple sclerosis, lesions are believed to occur when activated inflammatory cells, including T lymphocytes, cross the blood–brain barrier (BBB). Leukocyte migration across the BBB involves interaction between adhesion molecules on inflammatory cells and their counterreceptors present on endothelial cells of the vessel wall. The clinical effect of natalizumab in multiple sclerosis may be secondary to blockade of the molecular interaction of α4β1 integrin expressed by inflammatory cells with VCAM-1 on vascular endothelial cells, and with CS-1 and/or osteopontin expressed by parenchymal cells in the brain. Data from an experimental autoimmune encephalitis animal model of multiple sclerosis demonstrate reduction of leukocyte migration into brain parenchyma and reduction of plaque formation detected by magnetic resonance imaging (MRI) following repeated administration of natalizumab. The clinical significance of these animal data is unknown. Tysabri is indicated as monotherapy for the treatment of patients with relapsing forms of multiple sclerosis to delay the accumulation of physical disability and reduce the frequency of clinical exacerbations. The safety and efficacy of Tysabri beyond 2 years are unknown. Because Tysabri increases the risk of progressive multifocal leukoencephalopathy (PML), an opportunistic viral infection of the brain that usually leads to death or severe disability, Tysabri is generally recommended for patients who have had an inadequate response to, or are unable to tolerate, alternate multiple sclerosis therapies. Safety and efficacy in patients with chronic progressive multiple sclerosis have not been studied. Tysabri should not be administered to patients with known hypersensitivity to Tysabri or any of its components. Tysabri is contraindicated in patients who have or have had PML.

**Lucentis (ranibizumab injection)** is a recombinant humanized IgG1κ isotype monoclonal antibody fragment designed for intraocular use [64, 65]. Ranibizumab binds to and inhibits the biologic activity of all VEGF-A isoforms and the biologically active degradation product, VEGF110. Ranibizumab has a molecular weight of approximately 48,000 Da and is produced by an *Escherrchia coli* expression system. The parent molecule of ranibizumab is the murine full-length monoclonal antibody A4.6.1. A first-generation humanized Fab of A4.6.1 was affinity matured using phage display technology to generate the Y0317 variant, also known as rhuFab V2 or ranibizumab, which increased its affinity for VEGF-A 140-fold. Ranibizumab binds to the receptor binding site of active forms of VEGF-A, including the biologically active, cleaved form of this molecule, VEGF110. VEGF-A has been shown to cause neovascularization and leakage in models of ocular angiogenesis and is thought to contribute to the progression of the neovascular form of age-related macular degeneration (AMD). The binding of ranibizumab to VEGF-A prevents the interaction of VEGF-A with its receptors (VEGFR1 and VEGFR2) on the surface of endothelial cells, reducing endothelial cell proliferation, vascular leakage, and new blood vessel formation. Lucentis is indicated for the treatment of patients with neovascular (wet) AHD. Lucentis is contraindicated in patients with ocular or periocular infections.

**Vectibix (panitumumab)** is a recombinant, human IgG2κ monoclonal antibody that binds specifically to the human EGFR [66, 67]. Panitumumab has an approximate molecular weight of 147,000 Da. Panitumumab is produced in genetically engineered mammalian CHO cells. The EGFR is a member of a subfamily of type I receptor tyrosine kinases, including EGFR (HER1, c-ErbB-1), HER2/neu, HER3, and HER4. EGFR is a transmembrane glycoprotein that is constitutively expressed in many normal epithelial tissues, including the skin and hair follicle. Overexpression of EGFR is also detected in many human cancers, including those of the colon and rectum. Interaction of EGFR with its normal ligands (e.g., EGF, transforming growth factor-α) leads to phosphorylation and activation of a series of intracellular tyrosine kinases, which in turn regulate transcription of molecules involved with cellular growth and survival, motility, proliferation, and transformation. Panitumumab binds specifically to EGFR on both normal and tumor cells and competitively inhibits the binding of ligands for EGFR. Nonclinical studies show that binding of panitumumab to the EGFR prevents ligand-induced receptor autophosphorylation and activation of receptor-associated kinases, resulting in inhibition of cell growth, induction of apoptosis, decreased proinflammatory cytokine and vascular growth factor production, and internalization of the EGFR. In vitro assays and in vivo animal studies demonstrate that panitumumab inhibits the growth and survival of selected human tumor cell lines expressing EGFR. Vectibix is indicated for the treatment of EGFR-expressing, metastatic colorectal carcinoma with disease progression on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing chemotherapy regimens. The effectiveness of Vectibix for the treatment of EGFR-expressing, metastatic colorectal carcinoma is based on progression-free survival. Currently, no data are available that demonstrate an improvement in disease-related symptoms or increased survival with Vectibix. Panitumumab has been approved in the United States and is currently awaiting registration in Australia, Canada, the European Union, and Switzerland for the treatment of patients with EGFR-expressing metastatic colorectal cancer who have disease progression on or following fluoropyrimidine-, irinotecan- and oxaliplatin-containing chemotherapy regimens. It is under clinical investigation as both monotherapy and in combination with other anticancer agents for the treatment of patients with various types of cancer.

**Soliris (eculizumab)** is a formulation of eculizumab, which is a recombinant humanized monoclonal IgG2/4κ antibody produced by murine myeloma cell culture and purified by standard bioprocess technology [68]. Eculizumab contains human constant regions from human IgG2 sequences and human IgG4 sequences and murine complementarity-determining regions grafted onto the human framework light- and heavy-chain variable regions. Eculizumab is composed of two 448-amino-acid heavy chains and two 214-amino-acid light chains and has a molecular weight of approximately 148,000 Da. Eculizumab, the active ingredient in Soliris, is a monoclonal antibody that specifically binds to the complement protein C5 with high affinity, thereby inhibiting its cleavage to C5a and C5b and preventing the generation of the terminal complement complex C5b-9. Soliris inhibits terminal complement-mediated intravascular hemolysis in paroxysma nocturnal hemoglobinuria (PNH) patients. A genetic mutation in PNH patients leads to the generation of populations of abnormal red blood cells (RBCs) (known as PNH cells) that are deficient in terminal complement inhibitors, rendering PNH RBCs sensitive to persistent terminal complement-mediated destruction. The destruction and loss of these PNH cells (intravascular hemolysis) results in low RBC counts (anemia), and also fatigue, difficulty in functioning, pain, dark urine, shortness of breath, and blood clots. Soliris is indicated for the treatment of patients with PNH to reduce hemolysis. Do not initiate Soliris therapy in patients with unresolved serious *Neisseria meningitidis* infection and patients who are not currently vaccinated against *N. meningitidis*.

## 6 MONOCLONAL ANTIBODIES UNDER CLINICAL DEVELOPMENT

We estimated at least 300 monoclonal antibodies under development for the treatment of various human diseases. The majority of antibodies in development unsurprisingly are in preclinical development. There are many more undisclosed antibodies in preclinical development. Table 2 listed mAbs that are currently in clinical trials phase 1–3. phase 1 and phase 1/2 consists of 61 clinical trials. The number of phase 2 programs is 95 slightly larger that that of phase 1. Table 3 lists the fewest programs are in phase III trials and in registration with many are already approved drugs on the market. The active antibody development programs have a wider therapeutic focus, spanning many therapy areas. However, the main focus still remains on the two therapy areas with the highest sales, oncology and immunodisorders.

**TABLE 2 mAb under Clinical Development**

| Development Stage | Targets | Brand/Code | Generic | Company | Partners | Therapy area | Indication | Antibody class |
|---|---|---|---|---|---|---|---|---|
| Phase 1 | Blys | LymphoStat-B | Anti-BLyS | CAT | HGS | Immuno-Disease | Lupus Erythematosis | Fully human |
| Phase 1 | C6 | Eculizumab | 0 | Alexion | Lonza | Immuno-Disease | Paroxysmal nocturnal hemoglobinuria | Unknown |
| Phase 1 | CanAg | Cantuzumab mertansine, huC242-DM1 | 0 | ImmunoGen | 0 | Oncology | Cancers | Conjugated |
| Phase 1 | CCR2 | MLN1202 | Anti-CCR2 | Millennium | 0 | Immuno disease | Rheumatoid arthritis | Humanized |
| Phase 1 | CD20 | Pretarget lymphoma | Anti-CD20 | NeoRx Corp | 0 | Oncology | Lymphoma B-cell | Conjugated |
| Phase 1 | CD3/EpCAM | Removab | Anti-EpCAM × anti-CD3 | TRION Pharma GmbH | 0 | Oncology | Ovarian carcinoma | Other |
| Phase 1 | CD4 | TNX-355 | Anti-CD4 | Tanox | Biogen | Infectious diseases | HIV | Humanized |
| Phase 1 | CD4 | TRX1 | Anti-CD4 | TolerRx | Genentech | Immuno disease | IDI | Humanized |

| Phase 3 | HER –2/neu | Osidem (IDM-1) | Anti-HER-2/neu | Medarex | IDM | Oncology | HER-2+ Ovarian Cancer | Conjugated |
| Phase 3 | human IgE | Xolair | Omalizumab | Tanox | 0 | Respiratory | Allergy | Humanized |
| Phase 3 | IL-2R | Zenapax | Daclizumab Anti-CD25 | Protein Design Labs | 0 | Immuno disease | Heart transplantation | Humanized |
| Phase 3 | IL-6 receptor | MRA | Anti-IL-6 receptor antibody | Chugai | 0 | Immuno disease | 0 | Humanized |
| Phase 3 | IL-6 receptor | MRA | Anti-IL-6 receptor antibody | Chugai | 0 | Oncology | 0 | Humanized |
| Phase 3 | Integrin $\alpha 4$ $\beta 1$ intergrin | ANTEGREN | Natalizumab | Biogen-IDEC | 0 | CNS | MS | Humanized |
| Phase 3 | mimics the GD3 epitope | BEC2 | Mitumomab | ImClone | Merck KGaA | Oncology | small cell lung carcinoma | Murine |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Phase 3 | MUC1 | R1549 | Pemtumomab | Antisoma | Roche | Oncology | Ovarian cancer | Conjugated |
| Phase 3 | TGF-beta2 | Trabio | Lerdelimumab/ CAT-152/ anti-TGFß2 | CAT | Integra LifeSciences | Other | Cataract (Eye Disorders) Glaucoma | Fully human |
| Phase 3 | TNF-a | CDP 870 | Anti-TNFa Ab | Celltech | Pfizer | Immuno disease | Rheumatoid arthritis | Fragment |
| Phase 3 | TNF-a | CDP 870 | PEG-anti-TNF-a Ab fragment | Nektar | Pfizer Celltech | Immuno disease | Rheumatoid arthritis | Fragment |
| Phase 3 | TNF-a | CDP870 | 0 | Pfizer | Celltech | Immuno disease | Rheumatoid arthritis | Fragment |
| Phase 3 | VEGF | Avastin | Bevacizumab-rhuMAb-VEGF | Genentech | Roche | Oncology | Metastatic colorectal cancer | Humanized |
| Phase 3 | VEGF | Avastin | Bevacizumab-rhuMAb-VEGF | Genentech | Roche | Oncology | Renal cell carcinoma | Humanized |
| Phase 3 | VGEF | Lucentis | Ranibizumab | Novartis | Genentech/ Roche | Immuno disease | Macular degeneration | Humanized |
| Phase 3 | VGEF | Lucentis | Ranibizumab | Novartis | Genentech/ Roche | Immuno disease | Macular degeneration | Humanized |
| Phase 3 | VGEF | Lucentis | Ranibizumab | Novartis | Genentech/ Roche | Immuno disease | Macular degeneration | Humanized |
| Phase 3 | Idiotype | CeaVac | Mimics the carcinoembryonic antigen | Titan Pharmaceuticals | 0 | Oncology | metastatic colorectal cancer | Unknown |
| Phase 3 | Integrin α4 β1 intergrin | Antegren transgenic | anti α4 intergrin | GTC Biotherapeutics | Elan | Immuno disease | MS, Crohn's disease | Fully human |

**TABLE 3 Current Phase III Chlinc Monoclonal Antibody Trials in the United States**

| Condition | Trial |
|---|---|
| Lymphome | Chemotherapy and Peripheral Stem Cell Transplant with or without Monoclonal Antibody therapy in Treating Patients with Non-Hodgkin's Lymphoma |
| Kidney cancer | Monoclonal Antibody Therapy (RencarexA) in Treating Patients Who Have Undergone Surgery for Non-Metastatic Kidney Cancer |
| Brain and central nervous system tumors | Isotretinoin with or without Monochlonal Antibody, Interleukin-2, and Sargramostim Following Stem Cell Transplantation in Treating Patients with neuroblastoma |
| Brain and central nervous system tumors | Combination Chemotherapy with or without Filgrastim before Surgery, High-Dose Chemotherapy, and Radiation therapy Followed by Isotretinoin with or without Monoclonal Antibody in Treating Patients with Neuroblastoma |
| Lymphoma | Combination Chemotherapy with Monoclonal Antibody Therapy in Treating Patients with Newly diagnosed Non-Hodgkin's Lymphoma |
| Lymphoma | Combination Chemotherapy Plus filgrastim with or without Rituximab in Treating Older Patients with Non-Hodgkin's Lymphoma |
| Leukemia | Combination Chemotherapy with or without Monoclonal Antibody Therapy Followed by Stem Cell Transplant in Treating Patients with Acute Myeloid Leukemia |
| Ulcerative colitis | Efficacy and Safety of Adalimumab in Subjects with Moderately to Severely Acute Ulcerative Colitis |
| Lymphoma | Cyclophosphamide, Doxorubicin, Etoposide, and Prednisone OR Cyclophosphamide, Doxorubicin, Vincristine, Prednisone, and Rituximab Followed by Vaccine Therapy Plus Sargramostim in Treating Patients with Stage II, Stage III, or Stage IV Follicular Lymphoma |
| Breast cancer | Combination Chemotherapy with or without Capecitabine and/orTrastuzumab Before Surgery in Treating Women With Stage I, Stage II, or Stage III Breast Cancer |
| Ulcerative colitis | Efficacy and Safely of Adalimumab in Subjects with Moerately to Severely Acute Ulcerative Colitis |
| Crohn's disease | Open-Lable Study of Adalimumab for the induction and Maintonance of Clinical Remission in Subjects with Moderate to Severe Conhn's Disease |
| Crohn's disease | Efficacy and Safely of Adalimumab in Pediatric Subjects with Moderate to Severe Conhn's Disease |
| Breast cancer | Trastuzumab with or without Paclitaxel in treating Women with Metastatic Breast cancer That Overexpresses HER2 |
| Leukemia | Cytarabine and Daunorubicin with or without Gemtuzumab Ozogamicin Followed by High-Dose Cytarabine Followed by Either Gemtuzumab Ozogamicin or No Additional Therapy in Treating Patients with previously Untreated De Novo Acute Myeloid Leukemia |
| Colorectal cancer | Comparison of Combination Chemotherapy Regimens with or without Cetuximab in Treating Patients Who Have Undergone Surgery for Stage III Colon Cancer |
| Colorectal cancer, metastatic cancer | Combination Chemotherapy with or without Cetuximab before and after Surgery in Treating Patients with Reaectable Liver Metastases Caused by Colorectal Cancer |
| Colorectal cancer | Cetuximab and/or Bevacizumab Conbined with Combination Chemotherapy in Treating Patients with Metastatic Colorectal Cancer |
| Renal cell carcinoma (kidney) | cG250 Monocional Antibody vs Placebo for Renal Cell Carcinoma |
| Rheumatoid arthritis | Safety and Efficacy of Intravenous ACZ885 and Oral Methotrexate Therapy in Patients with Early Rheumatoid Arthritis |
| Muchle–Wells syndrome | Efficacy, Safety, and Tolerability of ACZ885 in Patients with Muckle-Wells Syndrome |
| Lymphoma | Rituximab in Treating Patients with Low Tumor Burden Indolent Non-Hodgkin's Lymphoma |
| Lymphoma | Combination Chemotherapy with or without Rituximab in Treating Older Patients with Non-Hodgkin's Lymphoma |
| Lymphoma | Rituximab in Treating Patients with Newly Diagnosed Stage II, Stage III, or Stage IV Follicular Non-Hodgkin's Lymphoma |
| Breast cancer | Trastuzumab for 6 Months or 1 Year in Treating Women with Nonmetastatic Breast Cancer That Can Be Removed by Surgery |
| Lymphoma | Rituximab in Treating Patients with Flooicular Non-Hodgkin's Lymphoma |
| Leukemla | Combination Chemotherapy with or without Gemtuzumab in Treating Yong Patients with Newly Diagnosed Acute Myeloid Leukemia |
| Lymphoma | Rituximab and Combination Chemotherapy in Treating Patients with Non-Hodgkin's Lymphoma |

**TABLE 3** ***Continued***

| Condition | Trial |
|---|---|
| Colorectal cancer | Combination Chemotherapy with or without Cetuximab as First-Line Therapy in Treating Patients with Metastatic Colorectal Cancer |
| Leukemia; myelodysplastic syndromes | Combination Chemotherapy with or without Gemtuzumab Ozogamicin or Tipifamib in Treating Patients with Acute Myeloid Leukemia or High-Risk Myelodysplastic Syndromes |
| Gastrointestinal stromal tumor | Imatinib Mesylate with or without Bevacizumab in Treating Patients with Metastatic or Unresectable Gastrointestinal Stromal Tumor |
| Breast cancer | Two Different Combination Chemotherapy Regimens Given with Trastuzumab in Treating Women with Palpable Breast Cance That Can Be Removed by Surgery |
| Leukemia | Combination Chemotherapy with or without Gemtuzumab Followed by Tretinoin, Mercaptopurine, and Methotexate or Observation in Treating Patients with Acute Promyelocytic Leukemia |
| Lymphoma | Rituximab and Combination Chemotherapy in Treating Patients with Diffuse Large B-Cell Non-Hodgkin's Lymphoma |
| Gastric cancer | Combination Chemotherapy with or without Bevacizumab in Treating Patients with Previously Untreated Stomach Cancer or Gastroesophageal Junction Cancer That Can Be Removed by Surgery |
| Prostate cancer | Docetaxel and Prednisone with or without Bevacizumab in Treating Patients with Prostate Cancer That Did Not Respond to Hormone Therapy |
| Colorectal cancer | Irinotecan and Cetuximab with or without Bevacizumab in Treating Patients with Metastatic Colorectal Cancer That Progressed During First-Line Therapy |
| Lymphoma | Rituximab and Combination Chemotherapy with or without Radiation Therapy in Treating Patients with B-Cell Non-Hodgkin's Lymphoma |
| Leukemia | Rituximab, Fludarabine, and Cyclophosphamide or Observation Alone in Treating Patients with Stage 0, Stage I, or Stage II Chronic Lymphocytic Leukemia |
| Leukemia | Early or Delayed Fludarabine and Rituximab in Treating Patients with Previously Untreated Chronic Lymphocytic Leukemia |
| Falloplan tube cancer, ovarian cancer; peritoneal cavity cancer | Carboplatin and Paclitaxel with or without Bevacizumab in Treating Patients with Stage III or Stage IV Ovarian Epithelial or Primary Peritoneal Cancer |
| Breast cancer | First-Line Chemotherapy and Trastuzumab with or without Bevacizumab in Treating Patients with Metastatic Breast Cancer That Overexpresses HER2/New |
| Colorectal cancer | Irinotecan with or without Panitumumab or Cyclosporine in Treating Patients with Advanced or Metastatic Colorectal Cancer That Did Not Respond to Fluorouracil |
| Esophageal cancer | Cisplatin, Capecitabine , and Radiation Therapy with or without Cetuximab in Treating Patients with Esophageal Cancer |
| Fallopian tube cancer, ovarian cancer; peritoneal cavity cancer | Carboplatin and Paclitaxel with or without Bevacizumab in Treating Patients with Newly Diagnosed Ovarian Epithelial Cancer, Fallopian Tube Cancer, or Primary Peritoneal Cavity Cancer |
| Lung cancer | Radiation Therapy and Cisplatin with or without Cetuximab in Treating Patients with Stage III or Stage IV Head and Neck Cancer |
| Colorectal cancer | Combination Chemotherapy with or without Bevacizumab in Treating Patients who Have Had Surgery for Stage II or Stage III Rectal Cancer |
| Breast cancer | Doxorubicin, Cyclophosphamide, and Paclitaxel with or without Bevacizumab in Treating Patients with Lymph Node-Positive or High-Risk, Lymph Node-Negative Breast Cancer |
| Lung cancer | Chemotherapy with or without Bevacizumab in Treating Patients with Stage IB, Stage II, or Stage IIA Non-Small Lung Cancer That Was Removed by Surgery |
| Colorectal cancer | Combination Chemotherapy and Bevacizumab with or without Eriotinib in Treating Patients with Metastatic Colorectal Cancer That Cannot Be Removed by Surgery |
| Type 1 diabetes mellitus | The Protégé Study—Clinical Trial of MGA031 in Children and Adults with Recent-Onset Type 1 Diabetes Mellitus |
| Lymphoma | Comparison of Two Induction Combination Chemotherapy Regimens Followed by High-Dose Consolidation Chemotherapy and Autologous Stem Cell |
| Colorectal cancer | Combination Chemotherapy with or without Cetuximab in Treating Patients with Stage III Colon Cancer That Was Completely Removed by Surgery |

(*Continued*)

**TABLE 3** ***Continued***

| Condition | Trial |
|---|---|
| Breast cancer | Chemotherapy with or without Bevacizumab in Treating Women with Stage I, Stage II or Stage IIA Breast Cancer That Can Be Removed by Surgery |
| Lymphoma | Comparison of Two Salvage Chemotherapy Regimens before Autologous Stem Cell Transplantation with or without Maintonance Rituximab in Treating Patients with Relapsed or Refractory Aggressive Non-Hodgkin's Lymphoma |
| Colorectal cancer | Oxaliplatin, Leucovorin, and Fluorouracil with or without Bevacizumab in Treating Patients Who Have Undergone Surgery for Stage II Colon Cancer |
| Mysosis fungoides; sezary | Study of Human Monoclonal Antibody to Treat Mycosis Fungoides and Sezary Syndrome |
| Lymphoma | Chemoradiotherapy and Peripheral Stem Cell Transplantation Compared with Combination Chemotherapy in Treating Patients with Non-Hodgkin's Lymphoma |
| Breast cancer | Adjuvant Doxorubicin, Cyclophosphamide, and Paclitaxel in Treating Patients with Breast Cancer |
| Melanoma; metastases | MDX-010 Antibody, MDX-1379 Melanoma Vaccine, or MDX-010/MDX-1379 Combination Treatment for Patients with Melanoma |
| Ulcerative colitis | Open-Label Adalimumab for Ulcerative Colitis Patients |
| Crohn's disease | Study of Adalimumab for the Maintenance of Clinical Remission in Japanese Subjects with Crohn's Disease |
| Crohn's disease | Study of Adalimumab for the Induction of Clinical Remission in Japanese Subjects with Crohn's Disease |
| Crohn's disease | Effects of Adalimumab on Mucosal Healing in Subjects with Crohn's Disease Involving the Colon |
| Lupus erythematosus, systemic; Lupus nephritis | TNF Blockade with Remicade in Active Lupus Nephritis WHO Class V (TRIAL) |
| Non-Hodgkin's lymphoma | Zevalin and BEAM High-Dose Chemotherapy Compared with BEM Alone as Conditioning Regimen in Patients with Chemosensitive Repapse of Non-Hodgkin's Lymphoma |
| Polyneuropathy associated with anti-MAG IgM gamopathy | RIMAG Study: Trial of Rituximab versus Placebo in Polyneuropathy Associated with Anti-MAG IgM Monoclonal Gammopathy |
| Membranoproliferative | Pilot Study of Rituximab for Membranoproliferative Glomerulonephritis |
| Renal transplantation | Efficacy and Safety of Enteric-Coated Mycophenolate Sodium and Cyclosporine in Combination with and without Steroids, in Adult Renal Transplant Recipients |
| Arthritis | Intraarticular Injection of Infliximab |
| Systemic lupus erythematosus | Study of Belimumab, a Fully Human Monoclonal Anti-BLyS Antibody, in Subjects with Systemic Lupus Erythematosus (SLE) |
| Systemic lupus erythematosus | Study of Belimumab, a Fully Human Monoclonal Anti-BLyS Antibody, in Subjects with Systemic Lupus Erythematosus (SLE) |
| Follicular Lymphoma | HuMax-CD20 in Follicular Lymphoma (FL) Patients Refractory to Rituximab |
| B-cell chronic lymphocytic | HuMax-CD20 in B-Cell Chronic Lymphocytic Leukemia (B-CLL) Patients Failing Fludarabine and Alemtuzumab |
| Head and Neck cancer; squamous cell cancer | Zalutumumab in Patients with Non-Curable Head and Neck cancer |
| Acute myeloid leukemia; myelodysplastic syndrome | To Determine the Role of Adding Campath-1H or ATG Given in-Vivo in Addition to Fludarabine and Low Dose Busulfex on Outcome in Patients Treated with Reduced Intensity Conditioning |
| Liver transplantation | Tacrolimus and Daclizumab versus Tacrolimus and Steroides in Liver Recipients Receiving Aub-Optimal Grafts |
| Non-Hodgkin's lymphoma | Study of Rituximab versus Iodine I 131 Tositumomab Therapy for Patients with Non-Hodgkin's Lymphoma |
| Large-cell, immunoblastic; lymphoma, Non-Hodgkin | Comparison of Rituxan versus Bexxar When Combined with Carmustine, Etoposied, Cytarabine and Melphalan (BEAM) with Autologous Hematopoietic Stem Cell Transplantation (ASCT) |
| Leukemia, myelocytic, acute | Treatment of Patients with Newly Diagnosed Acute Myeloid Leukemia or Myelodyspiasia |
| Hypereosinophilic syndrome | Compassionate Use of Mepolizumab in Subjects with Hypereosinophilic Syndrome (HES) |
| Metastatic breast neoplasm | Vinorelbine+Trastuzumab vs Docetaxel+Trastuzumab as 1. Line Treatment for HER2+ Metastatic Breast Cancer |

**TABLE 3** ***Continued***

| Condition | Trial |
|---|---|
| Macular degeneration; choroidal neovascularization | Efficacy and Safety of Verteporfin Photodynamic Therapy Administered with Ranibizumab in Patients with Subfoveal Choroidal Neovascularization |
| Acute myeloid leukemia | Efficacy/Safety of Verteporfin Photodynamic Therapy and Ranibizumab Compared with Ranibizumab in Patients with Subfoveal Choroidal Neovascularization |
| Acute myeloid leukemia | NOPHO-AML 2004 Study for Children with Acute Myeloid Leukemia |
| Diabetic macular edema; visual acuity; dlabetic retinopathy | Zevalin-Beam for Aggressive Lymphoma |
| Diabetic macular edema; visual acuity; dlabetic retinopathy | Treatment of Refractory Diabetic Macular Edema with Infliximab |

## 1 INTRODUCTION

### 1.1 Overview

***What Is a Drug?*** The U.S. Food and Drug Administration (FDA) defines a drug as: "(A) articles recognized in the official United States Pharmacopeia, official Homeopathic Pharmacopeia of the United States, or official National Formulary, or any supplement to any of them; and (B) articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals; and (C) articles (other than food) intended to affect the structure or any function of the body of man or other animals; and (D) articles intended for use as a component of any articles specified in clause (A), (B), or (C)" [http://www.fda.gov/opacom/laws/fdcact/fdcact1.htm, Chapter II—Definitions, (g)(1)].

While this rather broad definition serves well for regulatory purposes for this chapter, the term *drug* must be narrowed to that more appropriate to the disciplines of pharmacology, pharmacy, and medicine. In this context, we will define a "drug" as a specific chemical species able to cause specific changes in the functioning of living things. More specifically, we will further narrow the definition to relatively small (<1500 Da) organic and occasionally inorganic compounds. This narrowed definition is not meant to indicate that the many macromolecular agents such as polyclonal or monoclonal antibodies or enzymes are of less value therapeutically, but merely recognizes the great difference between macromolecules and smaller discrete organic or inorganic molecules.

***Pharmacokinetics, ADME, and Drug Properties*** Drugs, essentially by definition, are chemicals that bring about specific, often very specific and very potent, biological responses in their target organisms. However, it is insufficient for a chemical to be either potent or specific. Drugs must have other properties. When a drug is administered, it will follow a reasonably predictable course of ***a****bsorption* into the body, ***d****istribution* throughout the body, possible enzymatic ***m****etabolism* of the drug, and ultimate ***e****xcretion* (ADME). These processes, together with drug ***t****oxicity*, constitute the common pharmaceutical acronym, *PK/ADMET*, with PK standing for *pharmacokinetics*, which is to say the time course of a drug into, through, and eventually out of the body; it is what the body does to the drug (versus *pharmacodynamics*, which is what the drug does to the body).

***Polarity and Drug Properties*** Pharmaceutical companies require certain properties of the drugs they discover, develop, and manufacture. Most importantly, drugs must be safe and effective. This is a trade-off. For some life-threatening diseases such as cancer or an acute serious infection, it is more important that a drug be effective than safe. On the other hand, drugs used very widely such as over-the-counter pain relievers or drugs taken regularly over years or decades for chronic conditions such as hypertension or osteoporosis are held to a much higher standard of safety.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

Beyond safety and efficacy, drug manufacturers desire that drugs be chemically stable, reasonably inexpensive, and easy to manufacture (this is often a fairly minor consideration since production costs often represent only a small fraction of the consumer costs of a drug), have favorable pharmacokinetic and metabolic profiles, and, importantly, be soluble to some extent in water or some aqueous formulation.

This aspect of drugs is dictated by the fact that they must function in living organisms, which are overwhelmingly composed of water. While there are many means of drug administration, the two most important ones are intravenous injection and most importantly, oral administration. For intravenous injection, a drug must either be soluble in a water-based formulation or must be able to be formulated as a stable suspension or colloid. For drugs taken orally, they ideally should have moderate solubility and be of moderate polarity. Highly polar molecules are generally very water soluble but pass very poorly through biological membranes via passive diffusion while very nonpolar molecules pass readily through membranes but are essentially insoluble in the fluids of the stomach and intestines where drug absorption occurs.

## 1.2 Drug Discovery and the *Pipeline*

Modern drug discovery is an extremely expensive and very long process with some sources stating that it takes an *average of* $800 million and 11–15 years to move a drug through ultimate FDA (in the United States) approval and final marketing. (There is some controversy about the numbers involved, but it is certainly both long and expensive.) The drug discovery and development process is illustrated in Figure 1 and is often referred to in the pharmaceutical industry as the *pipeline*.

The pipeline usually starts with identifying an appropriate disease state on which to focus corporate resources (itself a very complex process) and find a corresponding *target* for that disease state. The target might, for instance, be an important enzyme present in a pathogenic bacteria or a receptor associated with a neurological disorder. An *assay* is developed, usually an in vitro assay, that will allow many synthetic or natural product chemicals to be tested or *screened* until a fairly small number of *hits* are found to have favorable properties in terms of potency and selectivity. At this point, however, it is unlikely that any one of those hits will have appropriate PK/ADMET properties in and of themselves. Thus, they will have to be chemically modified to improve PK/ADMET and other properties (ease and cost of synthesis, chemical stability, etc.). This process converts hits into *leads*, or compounds that are likely to be good drugs. The leads are evaluated against a large battery of tests, both in vivo and in vitro, such as toxicity in animals, likelihood of crossing the gut wall (for oral drugs), the *blood–brain barrier* (BBB) (a specialized brain capillary structure that prevents most chemical species in the blood such as drugs and many endogenous species to reach the brain while still allowing essential species such as glucose to reach the brain). This is generally an iterative process and is nearly always very expensive and time consuming. Eventually a single lead structure will be identified as a drug *candidate* that will be moved forward into human clinical trials. Thus, the whole process of drug discovery and development involves a constant winnowing, wherein many, sometimes millions, compounds are tested and only one or a very few emerge as approved drugs.

***Sources of Drugs*** Drugs are used everywhere in our society and throughout the world. They have been used in one form or another for all recorded history (as herbs or herbal preparations). Their uses range from legitimate medical use (where the pharmaceutical industry prefers the term "medicine," believing it to have a less pejorative connotation) to illegal "recreational" use, as well as veterinary, animal husbandry, and sports enhancement (both legal and illegal) uses. Currently, small-molecule drugs can be broadly classified as (1) natural product drugs, (2) synthetics drugs, and (3) semisynthetic drugs. Natural product drugs were the first drugs used. This was well before the concept that dis-

**Figure 1** *Pipeline* of drug discovery starts with identifying a disease-related *target* for which a quantitative assay can be developed such as a relevant enzyme or receptor. A bioassay is developed and a great many chemicals are assayed until one or more *hit* chemicals are found, which is to say a chemical structure that is likely to be both potent and selective as a drug. These compounds can be synthetically modified to improve PK/ADMET properties to generate *lead* structures, only a very few of which will be chosen as drug *candidates* to be advanced into human clinical trials.

crete chemicals even existed, and they continue to be used in impure preparations by indigenous healers worldwide. Natural product drugs are produced by various organisms such as microbes and fungi but also plants and animals with a more recent focus on marine organisms. Synthetic drugs are produced wholly by chemical synthesis, and semisynthetic drugs represent a fusion of the two, as either a synthetic chemical modification of an existing natural product or a de novo chemical synthesis of a current natural product or of a related structure.

***Natural Product Drug Discovery*** Natural products and their derivatives are the single most important source of anticancer agents. Natural product drug discovery programs reflect the philosophy that chemical compounds derived from nature "far exceed the imagination and synthetic capabilities of medicinal chemists," a view born out by the great structural complexity and wide range of mechanisms of action found among these agents [1]. To date, more than 40% of all drugs are either natural products or semisynthetic derivatives of natural products. Indeed, 61% of small-molecule *new chemical entities* (NCEs, an active chemical species that has never been previously approved in any form) introduced as drugs from 1981–2002 can be traced to natural products. For certain categories this is higher such as for anticancer agents where it is 74% and antibacterial agents where it is 79% [2].

Natural products exhibit truly remarkable diversity in chemical structure. The overwhelming majority of natural products with pharmacological activity are *secondary metabolites* (SeMes) [3, 4]. Secondary metabolites are cellular chemical products with no recognized essential metabolic function in growth or reproduction, but they play important roles in the ecological interactions of an organism and are probably ubiquitous in nature [5, 6]. Rather, secondary metabolites are expressed during times of microbial stress and are thought to provide the microbe protection from predators, assisting the microbe by protecting a nutritive source from foreign microbial invasion as well as playing many other important biological roles.

Secondary metabolites can be grouped into large chemical classes. Cavalier-Smith [7] distinguishes 13 major classes of SeMes derived from primary metabolic pathways (acetyl-Co-A, amino acids, purines, etc.), which are distinct and specifically distributed among 8 major phylogenetic clades. A similar classification is found in antibiotic classification with 10 antibiotic families and approximately 500 discrete groupings [8]. In a broader natural product classification of 17 classes over 500 subgroupings have been defined [9]. Classification of antibiotics and natural products reflect a compromise in classifying a great array of chemical species according to their primary metabolic source, evolutionary development, and chemical features.

Secondary metabolites are synthesized by specialized, well-coordinated multigene systems that are often clearly derived from some past primary metabolic systems in response to prolonged evolutionary pressure [10]. Because of these features, production of any given SeMe exhibits very narrow taxonomic distribution with a given chemical substance rarely being produced by more than a few related genera and frequently by only a single species or strain in a genus. This narrow taxonomic range has driven drug discovery into ecosystems that exhibit great and/or novel biodiversity. Thus, one sees efforts in tropical and temperate rainforest, caves, coral reefs, other exotic or "extreme" ecosystems. For instance, the very important anticancer agent paciltaxel was isolated by Wall and Wani in 1967 from the bark of the Pacific yew tree (*Taxus brevifolia*), which grows in North American temperate rainforests [11].

Discovery of natural problem drugs is very difficult. The isolation procedures often are tedious, labor intensive, poorly amenable to automation, and highly customized for each natural product. They ultimately depend on bioassays. Such assays require biological activity be identified in an iterative fashion with multiple separation fractions and the assays are often slow and show poor reproducibility. Also, natural products must be isolated from biological material. This often does not represent a problem for antibiotics or other agents that can be grown in very large amounts in fermentation vats but may be very problematic in other cases where the source material may be present in very limited quantities. Indeed, there was concern that isolation of paciltaxel in sufficient quantities to treat large numbers of patients would drive the Pacific yew tree to extinction (paciltaxel is no longer obtained from the yew tree). Also, it can take very large quantities of starting material to obtain small quantities of active material. Again, paciltaxel is illustrative; it took almost 1200 kg of bark to yield 10 g of pure material [12]. Accessing biodiverse sites in development nations can also be problematic. Developing, and indeed most, nations are justifiably very protective of their biodiverse heritage and fear that large American and European pharmaceutical companies may exploit the genetic and biodiversity without compensation. The UN Convention on Biodiversity restricts access to areas such as tropical rainforests without appropriate negations and agreement [13].

Even after biological material is obtained and a pure compound is isolated, elucidating the full chemical structure is not trivial even with high-resolution mass spectroscopy and advance multidimensional nuclear

magnetic resonance (NMR). Even with a fully elucidated structure in hand, there is another serious problem: *dereplication*. Dereplication refers to identifying and eliminating from any further drug discovery activities active agents that have been previously identified. This is a key step in natural product drug discovery. As early as 1985, Berdy reported more than 95% of chemicals that were isolated from surface-soil microbes had been previously recorded [14]. Despite the great success of natural products as drugs, given all the above limitations, natural products began to lose their allure for pharmaceutical companies.

***Traditional Synthetic Drug Discovery*** Historically, the birth of drug discovery dates to 1846 when the explosive and antianginal agent nitroglycerin was first synthesized by the Italian chemist A. Sobrero by adding glycerol to a mixture of concentrated nitric and sulfuric acids. He observed that a small amount placed on the tongue gave a severe headache. In 1847 C. Hering developed the sublingual dosage form. Subsequently, in 1857 an Edinburgh physician, T. L. Brunton, administered amyl nitrite, a known vasodepressor, by inhalation and noted transient anginal pain relief. In what may be the first instance of true medicinal chemistry, W. Murrell deduced that the action of nitroglycerin mimicked that of amyl nitrite and helped establish the use of sublingual nitroglycerin for relief of the acute anginal attack. Ironically, Alfred Nobel developed dynamite in the 1860s by combining liquid nitroglycerin with an inert porous material. Later he would use nitroglycerin for anginal pain. Nobel died in 1896 of a cerebral hemorrhage and left the bulk of his fortune in trust to establish the Nobel Prizes. In 1998, the Nobel Prize in Medicine or Physiology was awarded to Furchgott, Ignarro, and Murad for recognizing the importance of nitric oxide (NO), which derives from nitroglycerin, as a signaling molecule. After its early beginning, synthetic chemical drug discovery became a fully developed arm of drug development. It drew heavily from the coal gas (and related coal tar) industry and the dye industry, particularly in Germany. It had a great (although very checkered) success in development of the first antibiotics in the 1930s, the *sulfa* or *sulfonamide drugs,* which well predated the use (but not discovery) of penicillin.

Synthetic drug synthesis is, of course, a subset of organic chemical synthesis. That should be well known to any person who has sat through an organic chemistry lecture or laboratory classes. As a means of making and discovering drugs, traditional chemical synthesis has many of the same limitations of natural product chemistry. As with natural product chemistry, even with modern instrumentation, it remains time and labor intensive, is generally poorly amenable to automation, and is also highly customized. While some parallel synthesis is common, many compounds must be made essentially "one at a time." As such, the number of chemical species that can be made, purified, and verified to have the desired structure remains limited. As with natural product isolation, synthetic chemists are highly experienced and often highly specialized, having focused much of their careers on synthesizing a limited number of molecular scaffoldings. These difficulties of both traditional synthetic chemistry and natural product chemistry provided a strong incentive to the development of combinatorial chemistry in the 1990s.

***Combinatorial Drug Discovery*** The basic concept of combinatorial chemistry is straightforward: A large (often very large) number of structurally different, but chemically related species are synthesized essentially simultaneously. To accomplish this, very similar or identical reaction conditions and reaction apparatus must be used. To perhaps better understand this, one can look back to the 1960s when Merrifield developed solid-phase peptide synthesis, an important antecedent of combinatorial chemistry [15].

Briefly, In Merrifield's *solid-phase peptide synthesis* (SPPS), fairly large (20–50 μm), chemically inert resin beads have the C-terminal amino acid residue of a nascent desired peptide chain covalently bound via a linker to the bead (beads with appropriated prelinked residues are readily commercially available). The α-amino group is protected with a labile group [commonly *tert*-butyloxycarbonyl (*t*-Boc) or 9-flourenylmethloxycarbonyl (Fmoc). The amine can be made available for further chemical coupling reactions with other residues by deprotection. The beads are loosely packed into small glass columns. A series of organic solvents, with or without subsequent residues or reactants, are pumped through the column in a sequential fashion in a series of steps as illustrated in Figure 2.

1. *Deprotection* The amine-protecting group is removed via a chemical reagent exposing the reactive amine.
2. *Wash* The deprotecting reagent (and removed protecting groups) is washed out of the column.
3. *Coupling* An amine(s)-protected residue is cycled through the column and a coupling reaction occurs between the amine of the unprotected immobilized reside and the carboxyl moiety of the amine-protected free residue. Steps 1–3 are repeated until the entire desired peptide is completed.

**Figure 2** In Merrifield's solid-phase peptide Synthesis (SPPS), an amino acid residue (represented as a circle) is bound covalently to a solid support via a linker. The α-amino group (N) is protected (represented as NP). The protecting group is removed chemically and a second protected residue is allowed to react and couple. The protecting group of this residue can then be removed and a third protected residue can be added. The process is repeated until the desired peptide is made, after which it can be cleaved from the resin, purified, and characterized.

4. *Cleavage, Deprotection, and Purification* At the end of synthesis, the peptide is cleaved from the bead, all amines are deprotected, and the peptide is purified, often by semipreparative high-performance liquid chromatography (HPLC).

Merrifield's SPPS (and other procedures like it) can only make one peptide at a time. However, in combinatorial chemical synthesis, a great many different (in this case peptides) chemical species can be made essentially at once. For instance, instead of just starting with beads that had just one residue, the chemist could start with a selection of beads that had all 20 natural occurring amino acids immobilized on them. In turn, these beads could be exposed to, and reacted with, all 20 amino acids at each cycle of the growing peptide. At the end one would have, at least in principle, all possible peptides of the given length.

Combinatorial chemistry (the term was first coined in the early 1990s, although research in combinatorial chemistry had been ongoing at Glaxo Wellcome Inc. under the direction of H. M. Geysen since 1984) did at first primarily focus on peptide and oligonucleotide *chemical or compound libraries.* A chemical or compound library is a collection, often very large, of stored chemicals usually used for drug screening purposes (and also other industrial purposes such the search for better catalysts). The library can consist of both synthetic and pure natural products or plant, microbial, or animal extracts and should always have a database with critical information such as quantity, structure, and purity associated with it.

The methods used for combinatorial synthesis are diverse and no longer limited to peptides or oligonucleotides. However, the concept remains the same; simultaneous synthesis of many new chemical species. Combinatorial chemistry gave a promise to the pharmaceutical industry of providing many NCEs to reduce the time and costs required for drug discovery.

## 2 CHEMICAL DIVERSITY

Chemical diversity represents the idea that, for new drug discovery, one should examine a great many small organic molecules that are different in as many chemical properties as possible. It is based on the observation that structurally similar compounds exhibit similar physicochemical and biological properties. Thus, if one wishes to discover new drugs with novel mechanism of action, one must examine as many structurally diverse molecules as possible.

### 2.1 Permutations, Combinations, and Possibilities

The concept, while simple in principle, is daunting if we actually examine how many molecules are indeed possible. To do this we need to look at the permutations, combinations, and possibilities available in small organic molecules.

Each different arrangement of all or part of a set is a permutation. The number of *permutations* of $n$ things taken $r$ at a time is

$$nPr = \frac{n!}{(n-r)!} \tag{1}$$

For instance, if one wants to determine the number of ways to arrange three amino acids, such as aspartic acid (Asp), phenylalanine (Phe), and alanine (Ala) in a

**TABLE 1 Combinations, Permutations, and Possibilities for Peptides of Various Lengths Made from the 20 Naturally Occurring Amino Acids**

| | Peptide Length | | |
|---|---|---|---|
| | 5 | 10 | 15 |
| Combinations | $1.6 \times 10^4$ | $1.9 \times 10^5$ | $1.6 \times 10^4$ |
| Permutations | $1.9 \times 10^6$ | $6.7 \times 10^{11}$ | $2.0 \times 10^{16}$ |
| Possibilities | $3.2 \times 10^6$ | $1.0 \times 10^{13}$ | $3.2 \times 10^{19}$ |

dipeptide, where order *does* matter and no amino acid can be repeated, there would be six permutations.

Each arrangement of all or part of a set without regard to order is a combination permutation. The number of *combinations* of $n$ things taken $r$ at a time is

$$nPr = \frac{n!}{r!(n-r)!} \tag{2}$$

For the same example, the number of ways to arrange the three amino acids in a dipeptide where order *does not* matter and no amino acid can be repeated would give three combinations. Of course, in biology order definitely does matter. One can note, for instance, that aspartame, the artificial sweetener, is the methyl ester of the dipeptide of the amino acids aspartic acid and phenylalanine, while the corresponding ester of the dipeptide of phenylalanine and aspartic acid is not a sweetener. Finally, all possible outcomes where a unit such as an amino acid can be repeated, which is to say the number of possibilities of $n$ things taken $r$ at a time is, $n^r$.

Consideration of this leads to insight on chemical diversity. For short peptides, much less proteins, made with the 20 naturally occurring amino acids, the numbers can rise very quickly, as seen in Table 1 wherein are shown the combinations, permutations, and possibilities for short peptides of various lengths. The task of examining chemical diversity is daunting indeed.

### 2.2 Chemical Space and Molecular Descriptors

Chemical space is a theoretical concept wherein all possible chemical species occupy an $n$-dimensional topography. Each "dimension" is represented by a *molecular descriptor*, which is quantitative values that transform the chemical information of a molecule into a number. These can be obtained from experimentally derived values such as $pK_a$, polarity (a log P value is the logarithm of the partition coefficient of a molecule between $n$-octanol and water and the M log P value refers to the experimentally measured value versus the calculated or C log P value), and molecular weight and the like. These descriptors represent properties of complete molecules. Other descriptors can be derived from various algorithms that perform two- or three-dimensional structural analysis of molecules. The former would include simple counts of molecular features such as the number and types of ring systems, the number of rotatable bonds, and so forth. An example of the latter would be spatial relationships between atoms, rings, and other planer structures. This requires generation of three-dimensional conformational models and generally must take into account molecular flexibility. Such modeling, particularly with the large data sets, can be expensive and is very computationally intensive. Any given type of descriptor (experimental, or two- or three-dimensional) is unlikely to be useful alone in drug discovery, and thus they need to be used in combination. In the context of drug discovery, the desire is to gain insight into how chemically diverse a given library is. A library is mapped into chemical space using its molecular descriptors, and it is generally highly desirable to have a very diverse library, which is to say one that occupies a large volume of chemical space. In three dimensions, a library can be visualized, and at least a qualitative appreciation of the chemical diversity of that library can be obtained. Figure 3 shows a three-dimensional expression of chemical space wherein is illustrated a diverse (Fig. 3B) and less diverse (Fig. 3A) library. Beyond three dimensions, measures of the chemical diversity of a library cannot be visualized, and various computational algorithms must be employed to give a measure of that diversity.

### 2.3 Lipinski's Rule of Five

Lipinski's rule of five is a specific set of molecular descriptors used to evaluate if a given chemical compound has properties that would make it likely to be an orally active drug in terms of PK and ADME properties but says nothing about the pharmacological activity of a chemical. It was based the observation of Christopher Lipinski that many drugs were relatively small lipophilic molecules with certain particular chemical properties [16]. In drug development, when a pharmacologically hit or lead structure needs to be optimized for PK and ADME properties, the rule is very useful and states that, in general, an orally active drug should have:

1. No more than 5 hydrogen bond donors
2. No more than 10 hydrogen bond acceptors
3. A molecular weight under 500 g/mol
4. A log P value of less than 5

**Figure 3** Chemical space is a theoretical concept. It represents the "space" that can contain all possible chemically stable small organic molecules. Molecules are mapped into chemical space by various molecular descriptors. The degree to which molecules in a chemical library spread through chemical space gives an indication of the diversity of that library. There can be many descriptors. In the example above only three descriptors are used: molecular weight, p$K_a$, and measured lop P (M log P). The library in (B) has greater chemical diversity than the library in (A) and would be a better library for a drug search because of this.

## 3. PRINCIPLES OF COMBINATORIAL CHEMISTRY

As noted previously, combinatorial chemistry is a means by which large numbers of structurally different compounds are made at a given time. The general goal is to generate a very large chemical library for drug discovery with the hope (often not realized) to cover a large region of chemical space. To accomplish this, many simultaneous chemical synthetic reactions must be done. This requires identical reaction conditions, including temperature, reagents, and solvents for many synthetic reactions that are being done in parallel. The principles of combinatorial chemistry are best illustrated with the following example.

### 3.1 Split-Pool Combinatorial Synthesis

There are many combinatorial methods including those that are proprietary. To illustrate the power of combinatorial chemistry, we will focus on a single method, *split-pool combinatorial synthesis*. Split-pool synthesis is a solid-phase method and is one of the best methods rapidly synthesizing large number of compounds. In split-pool synthesis, a large library can be made quickly from a relatively few initial chemical building blocks, as illustrated in Figure 4. In the figure, three different building blocks (X, Y, and Z) are immobilized to a resin bead in a manner analogous to Merrifield's solid-phase peptide synthesis. Following immobilization, the beads are pooled then split into three (or as many building

**Figure 4** Split-pool combinatorial chemistry. In this combinatorial method, initial combin-atorial building blocks, X, Y, and Z in this case, are first immobilized on a solid support (resin beads) by the first chemical reaction in separate reaction vessels. The beads are then pooled, thoroughly mixed, and then split into new reaction vessels. To these reaction vessels are added the building blocks, which are allowed to couple to the previous building blocks, thus forming a growing chain. This process can be repeated through many cycles. The final number of theoretical individual chains can be very large. For a 10-mer polypeptide it would be approximately $1.0 \times 10^{13}$ unique peptides.

blocks as are being utilized) and reacted again with the building blocks. By this point there are now 6 unique products. After the next round of pooling, splitting, and reacting, there are 27 unique products. The cycles can be repeated as desired. In principle, all possible products of a given length, as determined by the number of cycles, should be synthesized. For a 10-mer with 15 building blocks, this would be $15^{10}$ ($n$ things taken $r$ at a time or $n^r$) or approximately $6 \times 10^{11}$ products; a truly enormous number.

The method has a number of limitations, the most important of which is determining which structure is on which bead; this will be addressed later in this chapter in the discussion of encoding. Depending on the synthesis, it can be irreproducible and have limited yield. Further, since no given coupling reaction is ever 100% efficient, every bead will have a heterogeneous mix of products representing the desired product as well as products where one or more coupling steps failed. For a 10-step synthesis with a 95% reaction efficiency, the final yield will be only approximately 60%. Thus, any observed bioactivity in a screen may not be in fact the result of the desired product but of one of the products where one or more coupling steps failed. Finally, because the building blocks must be synthetically compatible and thus probably structurally similar, the number of products produced may be very large, but the actual chemical diversity of the library may actually be quite limited.

### 3.2 High-Throughput Screening

The development of combinatorial chemistry was accompanied by the development *high-throughput screening* (HTS) techniques in the pharmaceutical industry. Clearly, if it is possible to make tens of thousands of compounds but there is no means to test them quickly and relatively inexpensively for bioactivity, combinatorial chemistry becomes an exercise in futility. High-throughput screening allows for tens to hundreds of thousands of small-molecule chemicals to be tested in days or weeks against a bioassay. High-throughput screening is characterized by high sample throughput and reduction of assay size so that assays can be run in microtiter plates. Microtiter plates are flat plates, usually of some form of plastic, and disposable. They have multiple wells that function essentially as very small test tubes. For HTS, the plates typically have 96, 384, or even 1536 sample wells arranged in a 2:3 rectangular array (6- and 24-well plates are also available and have many experimental uses). The wells have sample volumes that range up to several hundred microliters. In HTS, robotics and near to full automation is necessary for sample handling and sample assay. Near continuous operation is also highly desirable. Because of the amount of data HTS produces, most data processing and archiving are also highly automated. It is beyond the scope of this chapter to discuss HTS in detail, but it is important to note that HTS is a billion-dollar industry and represents a sea change in the means through which drugs are now discovered.

## 4 SOLID-PHASE SYNTHESIS

As noted previously, solid-phase combinatorial synthesis can be traced back to Merrifield's research in the 1960s where peptides, immobilized on resin beads, could be generated by sequential step-by-step reactions. In contrast to conventional organic liquid–liquid synthesis, reactant and solvents are readily removed by filtration, decanting, centrifugation, and the like. While initially applied to peptides, solid-phase synthesis (SPS) was then used for synthesis of other directionally aligned (i.e., 3′ to 5′ for oligonucleotides) biopolymers such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and related polymers such as phosporothioate oligonucleotides that are used for antisense chemotherapy. It was later used in combinatorial chemistry and has been largely responsible for the great growth in the field for both development of new drugs but also for synthesis of nondrug species such as catalysts.

The basic scheme in SPS is illustrated in Merrifield's method. Building blocks of a desired polymer such as amino acids with at least two functional groups are used. A starting building block is covalently linked to a solvent-insoluble polymeric support, which will withstand the synthetic reaction conditions. The binding is done via a linker that optimizes the reaction, for instance, by providing greater access to solvents and reactants to the growing polymer chain. The linker must also be such that it can be selectively cleaved from the resin at the end of the synthesis.

Of the two functional groups, one must usually be protected by a protecting group. At the start of the reaction, the protecting group of the first building block is removed, excess reactant is washed away, and the second building block is introduced and allowed to couple the first building block. The coupling reagents and reactants are washed away and the process is repeated until the desired polymer is completed. The polymer is then cleaved from the resin, purified, and characterized. Of note is that at each step of the polymer formation, errors will be introduced. As noted before, even under optimized reaction conditions, any given building block may fail to successfully couple to a previous one.

**Figure 5** Chemical structures associated with linkers for solid-phase combinatorial chemistry: (A) polystyrene, (B) amino acid reacted with chloromethylbenzene, (C) and (D) wang linker (C) before and (D) after attachment of the first building block, (E) rink linker, (F) trityl linker, (G) tetrahydropyran linkers, (H) silicon linker, and (I) photocleavable linker.

### 4.1 Resins

***Polystyrene*** Polystyrene (PS) (polymerized styrene; Fig. 5A) is the most common resin employed in SPS. The SPS supports are small spheres that are reasonably rigid and resistant to compression (unlike, e.g., agarose beads), insoluble to reaction solvents, and chemically stable to the reaction and porous to allow for much greater synthetic surface area. They are also functionalized (typically with chloromethyl or aminomethyl groups) so that linkers and starting building block molecules can be covalently attached. Commonly, styrene is lightly cross-linked (1–2%) with divinyl benzene (PS-DVB) or oxymethylene to produce poly(styrene-oxyethylene) graft copolymers. Polystyrene resins swell considerably on exposure to many organic solvents that commonly used SPS. This opens up the structure of the bead and allows easier diffusion of reactants, which both speeds the reaction and increases yield. The major exceptions to this are polar solvents such as alcohols, which do not cause appreciable swelling. This lack of swelling does not allow reaction sites to be at a sufficient distance from a hydrophobic resin core of PS-DVB beads.

***Polyacrylamide*** Polyacrylamide supports have been utilized with the polar solvents commonly used in peptide synthesis. These resins have amide functional groups that are similar to the peptide bonds present in proteins.

***Poly(Styrene-Oxyethylene) Copolymers*** Poly(styrene-oxyethylene) graft copolymers are also used commonly in SPS, also with a view to allow synthesis with more protic solvents. They are marketed under the name TentaGel and consist of polyethylene glycol attached via an ether linkage to cross-linked polystyrene. This class of resin swells in a wide variety of polar and non-polar solvents and is available commercially with a wide variety of linker groups. The polyethylene glycol gives the resin a polar character, but they retain the favorable features of polystyrene. The polymers have long flexible ethylene oxide chains branching off from the polystyrene backbone, which allows the synthetic reaction site to be distant from the hydrophobic bead core.

### 4.2 Linking Groups

The final element in making a good SPS support resin is the linking group. Liking groups connect the combinatorial building block to the solid support. The linking group must not cleave prematurely during the steps of the synthesis and must protect the connecting functional group(s) of the building block. Only at the end of the synthesis must the linker be cleaved, preferably easily and at high yield. The linking group should also allow ready attachment of the building block. Many linkers (at least 200) have been devised over the years. Given this, no attempt will be made at completeness and only a few very important or interesting linkers will be discussed here. Guillier et al. have produced an excellent and comprehensive review and should be consulted by interested readers [17].

***Strong and Mild Acid-Cleaved Linkers*** Carboxylic acid linkers were first used by Merrifield. Merrifield's resin beads were PS with a nitrated chloromethylpolystyrene. The free carboxylic acid of an *N*-protected amino reacted at the chlorine, giving a stable ester bond linkage of the first amino acid residue to the resin. Figure 5B shows the result of a reaction of an amino acid residue to chloromethylbenzene. At the end of the synthesis, HF was commonly used for cleavage.

Use of HF is very hazardous, although it does give good yields and purity. Partially to avoid the use of HF, a number of other methodologies were developed that required less acidic (relatively) conditions. Ease of cleavage of the linker under conditions of acid cleavage is related to the stability of the carbocation that is

formed upon cleavage. It was reasoned that addition of groups able to donate electrons would decrease the acid strength necessary for cleavage. This resulted in the development of the Wang and SASRIN (superacid sensitive resin) and Rink linkers [18–20, respectively].

Wang linkers are generally used with PS, TentaGel, and polyacrylamide resins. With its activated benzyl alcohol design, cleavage can be done in a less acidic environment using trifluoracetic acid (TFA; 50% in $CH_2Cl_2$ for 30 min). The Wang linker is the standard support for much peptide synthesis. Figures 5C and 5D show the Wang linker before (Fig. 5C) and after (Fig. 5D) attachment of the first building block or residue. The SASRIN linker is structurally very similar to the Wang linker but is made more acid-labile by the addition of one or more methoxy groups to enhanced stabilization of the carbonium ion formed during cleavage and can be cleaved with 1%–5% TFA. Finally, introduction of alkoxy groups gives the Rink linker (Fig. 5E), which can be cleaved under very gentle conditions (10% acetic acid or 0.2% TFA).

***Trityl and Tetrahydropyran Linkers*** Trityl linkers (Fig. 5F) were initially developed in the 1970s [21, 22]. The trityl group is an acid-labile protecting group for many heteroatoms. It has been used to anchor one alcohol group of a diol and has been used to synthesize a library of β-mercaptoketones. In peptide chemistry, the problem of the formation of racemates can be avoided during addition of the first residue using these linkers. Additionally, cleavage with dry TFA, HBr, or HCl is not difficult. A hydroxyl linker based on the tetrahydropyran protecting group was developed by Thompson and Ellmann [23] (Fig. 5G). Alcohols readily couple to dihydropyran, and the resulting tetrahydropyran protecting group is stable to strong bases and nucleophiles. It is easily cleaved by employing TFA/water (95:5, 15 min) and produces reasonable yields (66 and 95%) for primary and secondary alcohols but poor yields (10%) for tertiary alcohols.

***Silicon Linkers*** Organic compounds incorporating silicon (organosilyl compounds) groups have become widely used since their introduction in the early 1970s. In combinatorial chemistry where there is a desire to make libraries of low-molecular-weight species that are not peptides, these linkers are useful. Although mainly used with heteroatoms, they can also be employed with carbon and are compatible with many synthetic methods. One such linker is shown in Figure 5H [24]. Because they do not require attachment via a carboxyl group as in peptide chemistry, they are sometime referred to by the unfortunate and inaccurate term as "traceless linkers" because the final compound may give no definitive "trace" to the linkage site on the solid phase. The availability of agents specific for silicon such as fluoride species also adds to their utility. Acidic cleavage of the C–Si bond is generally quantitative and selective.

***Photocleavable Linkers*** Using light as a means of bond cleavage (photolysis) is very attractive. In principle, it should be gentle, can be used at neutral pH, and offers a means of deprotecting functional groups independently of one another (orthogonal deprotection). Photolysis has been widely used with biopolymers such as peptides, carbohydrates, and oligonucleotides. Use in nonoligomeric combinatorial chemistry is limited to some extent because many small organic compounds of medicinal interest absorb light or are photolabile at the wavelength(s) needed for cleavage. Ideally, the wavelengths used should only be absorbed by the linker and not cause generalized photodegradation. One of photocleavable inkers is shown in Figure 5I. It was found to be suitable for the preparation of protected peptides and could be cleaved by irradiation at 350 nm in an orthogonal fashion without degradation of the aromatic amino acids [25].

## 5 ENCODING

The ability of combinatorial methods to synthesize many thousands of discrete compounds very quickly has, as in all things, both pluses and minuses. While a great many compounds can be made for subsequent HTS, the chemical structure of any hit must, of course, be able to be determined. In combinatorial chemistry, this is not a trivial problem. For instance, in split-pool synthesis, each resin bead will, in principle, have a single unique compound attached to it but the structure of that compound will not be known. To determine that structure, various methods have been developed that allow the information relating to the actual synthesized species to be encoded on each bead.

### 5.1 Positional Encoding

Encoding can perhaps best be illustrated with an example. Positional encoding was first used by Geysen et al. in combinatorial synthesis [26]. The solid-phase support was an array of pins fixed in a simple matrix on a polypropylene rack. Unlike split-pool synthesis, the pins were not randomized, and thus the actual physical position of each pin served as the code for each compound. Thus, if pin 1 went through a series of steps, components A, B, C, and so on were added in sequential order, whereas pin 2 had A, C, and B added in that order, then after cleavage, the product from pin 1 should

be A–B–C while that from pin 2 should be A–C–B (provided in each case the synthesis proceeded correctly). The cleaved products from each pin would then be screened and any hit would be resynthesized as conformation. This method is one of the oldest and still the most widely used in automated robotic synthesizers. However, it has a number of limitations, the greatest of which is that only a relatively few number of compounds can be made owing to space limitations. While first employed with peptide libraries, this type of encoding is the method currently used for DNA microarrays where it has found its greatest utility.

### 5.2 DNA-Based Tagging

DNA-based tagging or encoding employs a strategy of dual synthesis on a support. The support resin has linkers on to which both an oligonucleotide and the combinatorial compound can be built. Orthogonal protecting groups allow a DNA tag to be made while the combinatorial compounds are also made. A polymerase chain reaction (PCR) primer is used as the linker between the support matrix and the DNA tag. With each new synthesis step, a new nucleotide is added to the DNA tag. At the end of the synthesis, a second PCR primer is added to the tag. After bioassays identify hits, the tag can be enzymatically cleaved and the tag can be amplified and sequenced. Because sequencing DNA is a very mature technology, the DNA sequence can be used to encode the combinatorial structure. Thus, if at the first split-pool step, components X were paired with adenosine [as adenosine 5′-triphosphate (ATP) for instance], Y with guanine, and Z with cytosine, every bead with an X would have a corresponding A, Y would have a corresponding G, and Z would have corresponding C. As the split-pool process continued, the growing oligonucleotide sequence would reflect the growing combinatorial sequence. If more than four possible combinatorial components are desired, multiple nucleotides can be incorporated with each reaction step. This method and all chemical tagging methods have the disadvantage that all bioactivity may result from the tag or some synergistic effect between the tag and the combinatorial compound.

### 5.3 Peptide Tagging

Peptides can also be utilized as tags in a way very analogous to DNA-based encoding with the tag sequences that can be decoded via Edman sequencing, and such an encoding strategy was developed by Kerr et al. at Chiron [27]. A lysine residue attached via a Rink amide linker to the solid support served as a bifunctional linker. Parallel synthesis of the combinatorial compounds and the coding peptides was possible by using orthogonal protecting groups. A base-labile Fmoc group was used on the α amine for the compound peptide while the mildly acid-labile protecting group, α, α-dimethyl-3,5-dimethoxybenzyloxycarbonyl (Ddz), was used on the ε amine. Four amino acids in a sequence of three residues ($4^3$ or 64 possible codes) were used to code for each combinatorial building block. After cleavage and identification of hits, sequencing allowed the hit structure to be decoded. The authors measured $IC_{50}$ (half maximal inhibitory concentration) bioactivity of both the product and tag to establish that the tag did not have activity. They tested the tag and product in combination and guarded against synergistic effects by noting the activity of product was similar to that of the product/tag combination.

### 5.4 Haloaromatic Binary Encoding

Binary encoding is an alternative to the oligomeric encoding of DNA-based and peptide tagging. Discrete chemical tags are used as binary "bits" to label each step of the combinatorial synthesis. This can perhaps best be understood by reference to Figure 6. In this example, pairs of tags are used to generate a series of binary identifiers. The presence of the first tag ($T_1$) and absence of the second tag ($T_2$) is encoded as 1, 0 and the presence of both $T_1$ and $T_2$ is encodes as 1, 1. New discrete chemical tags are incorporated at each step in the combinatorial cycle. At the end of the combinatorial synthesis, the tags are cleaved from the solid support and analyzed, for their presence or absence, to generate binary codes. This method has the advantage in that only a small proportion of a resin bead need be functionalized with a tag. However, the tags must be very chemically stable, not interconvertible, and readily and unambiguously detectable by appropriate means.

One method of binary tagging uses haloaromatic molecules (also called "hard" tags for their chemical stability). These tags were reported by Ohlmeyer et al. [28]. The tags were generated by the reaction of halophenols with bromo-alkanols. A great advantage of these tags was their ability to be separated via gas chromatography (GC) and detected with great sensitivity (0.1 pmol) with electron capture detection (ECD). This allowed the tags to be present at approximately 1% of the product, which greatly reduces the possibility of the tag interfering with the bioassay. One approach to enhance separation was to attach the tag via a photo-labile bond. After irradiation (366 nm), the released tags were chemically trapped via reaction with bis(trimethylsilyl)acetamide, which resulted in chemical derivatization of the tags (via reaction with the trimethylsilyl group, a common strategy used in GC to increase

**Figure 6** Binary encoding with split-pool synthesis. In this example, split-pool synthesis proceeds through two cycles generating nine products from three (X, Y, and Z) building blocks. To determine which product resides on which bead, information is encoded on each bead in the form of a series of chemically distinct binary tags ($T_1/T_2$ and $T_3/T_4$ as shown) with $T_1/T_2$ being used for the first cycle and $T_3/T_4$ used for the second cycle. (Subsequent cycles would need further pairs of distinct tags, e.g., $T_5/T_6$, $T_7/T_8$, etc.) At the end of the synthesis, the tags are cleaved from the solid support and appropriate methods (GC with ECD, e.g., with haloaromatic tags) are used to determine if a given tag is present on a given bead. The presence or absence of the tags is a binary code that can be used to decode the corresponding combinatorial products on the bead.

volatility of the analytes) and allowed direct analysis of the derivatized tags by GC-ECD.

### 5.5 Radiofrequency Encoding

Radiofrequency (RF) encoding or electronic encoding avoids problems associated with various chemical encoding schemes such as synthetic limitations or bioassay interferences arising from the presence of chemical tags [29]. This type of encoding uses very small electronic devices called radio frequency (RF) memory tags. These tags are in the millimeter range and are encased in sturdy plastic or glass sheaths. The tags are passive; they have no internal power source. Rather they contain an internal rectifying circuit that can absorbed RF energy and converted it to direct current (DC) electrical power. By appropriately irradiating the tag with external RF radiation and placing an antenna interfaced to a computer to record and analyze the passive signal, the tag can be "interrogated" as to its nature. Each tag can be so manufactured as to give a signal signature unique from all other tags. A solid-phase combinatorial structure such as a bead or bag of beads carrying an RT tag can be explicitly and automatically tracked through each reaction step. This allows the entire combinatorial sequence to be reconstructed and the products to be deduced. This technology is by no means exotic, difficult, or overwhelmingly expensive. Similar tags are used to track pets, livestock, pallets of merchandise, and the like and may greatly simplify combinatorial chemistry.

## 6. FUTURE OF COMBINATORIAL CHEMISTRY AND DRUG DISCOVERY

Combinatorial chemistry is a technology for creating large, sometimes extraordinarily large, numbers of small potentially druglike molecules for use in screening. Its roots lie, at least in part, in the increasing difficulty of traditional synthetic and natural product chemistry to generate new drugs in the 1980s and 1990s. However, the ability to generate $10^6$ (or even $10^7$) new chemicals does not mean that those molecules will be well distributed across chemical space, a fact generally not well appreciated at the time that combinatorial chemistry was rapidly developing. Virtually every large pharmaceutical company has invested in combinatorial chemistry, often very substantially, and the fruits of the money and effort have been impressive in terms of both chemistry and technology. Combinatorial chemistry has not been without its success, but it has not opened a flood gate to a wealth of new drugs as some of its early proponents once dreamed. It is not the "magic bullet" of drug therapy any more than liposomes (two drugs on the market), antisense oligonucleotides (one drug on the market), gene therapy (zero drugs on the market), or nano-this or nano-that (no drug even close to market) are. For those familiar with the early days of natural product drug discovery, there was also euphoria at that time that a great wellspring of new drugs had been discovered. Indeed natural products have been a much more generous source of drugs than combinatorial chemistry has been so far, but that spring is not infinite and the discovery of new natural products will require great effort. Combinatorial chemistry, along with natural product and traditional synthetic and medicinal chemistry, is a most welcome and important tool, and one

long to remain in our arsenal in the fight against disease. However, it cannot stand alone. It is highly doubtful we will ever find the next penicillin in a neglected Petri dish; those days are long gone. In new drug discovery, we must depend on careful painstaking science and hard thought, work, and decisions; serendipity and sophisticated technology have their place, but they are no substitutes.

## 7 KEY POINTS

1. The two main sources of drugs are natural products and synthetic drugs.
2. The PK/ADME properties of a drug must be considered along with the drug's efficacy and toxicity.
3. Combinatorial chemistry is a means of generating a great many new synthetic compounds, usually by massive parallel synthesis.
4. For drug discovery, the best chemical libraries are those that cover as much of chemical space as possible.
5. Combinatorial chemistry and HTS could not survive without one another.
6. Some means of encoding information on the synthetic steps of a combinatorial synthesis is critical to determining the resultant product structure.

## 8 REVIEW QUESTIONS

1. List advantages and disadvantages of natural product drugs.
2. Do the same for synthetic drugs.
3. What is meant by chemical diversity and chemical space?
4. Calculate the permutations, combinations, and possibilities for 12-mer polypeptides.
5. List the rule of five. What is it used for?
6. Explain Merrifield's solid-phase peptide synthesis; use diagrams as needed.
7. Explain split-pool synthesis; use diagrams as needed.
8. Which is, and why, the best resin to be used with polar solvents?
9. What is the purpose of a linker?
10. What is encoding and why is it important?
11. Explain oligomeric tagging.
12. Explain binary tagging.

## 1 INTRODUCTION

### 1.1 Values of Molecular Imaging in Cancer Treatment

Drug discovery and development are accelerating due to rapid synthesis of potential drugs and development of high-throughput in vitro tests. The development of radiolabeled biochemical compounds and imaging devices to detect the radioactivity by external imaging has expanded the use of nuclear medicine studies in drug development. Agents developed for positron emission tomography (PET) and single photon emission computed tomography (SPECT) are molecular imaging agents because they can characterize the disease. Since molecular imaging plays a major role in drug development because of its ability to quantify drug properties in vivo, it is beginning to be used in all phases of drug discovery and development. PET and SPECT agents show high specific activities because they are made through a nuclear transformation and use carrier-free forms of isotopes. PET and SPECT agents do not produce detectable pharmacologic effects but provide important information concerning the characterization of varieties of tumors (vascular angiogenesis, hypoxia, apoptosis, cellular signaling, and transcriptional activity) [1–8]. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound are prognostic tools because they do not provide cellular target information. Thus, assessment of the effectiveness of cancer therapy is not optimal. However, combining the anatomical and morphological location from CT, PET/CT and SPECT/CT are able to accurately evaluate posttherapy anatomic alteration. In addition, PET and SPECT agents may assist in the determination of optimal therapeutic dosing, differential diagnosis between inflammation/infection and recurrence, sensitive or resistant to treatment response, grading of tumors, and the prediction of treatment response by selecting patients who may respond to therapy.

### 1.2 Radiotheranostic Isotopes for Image-Guided Locoregional Chemoradiotherapy

Radiation therapy (XRT) is a form of cancer treatment that uses ionizing radiation to destroy cancer cells. Roughly 60% of all cancer patients receive XRT for multiple cancers including lung, breast, prostate, and head and neck. XRT can be delivered via external beams (photon, proton, neutron, and boron–neutron capture therapy) or internally using brachytherapy seeds. Conventional external beam radiation plays a limited role in the management of patients with certain nonresectable tumors because the maximum tumor dose is limited by the normal tissue tolerance [9]. Internal radiation therapy (IRT) with iodine-125 ($^{125}$I) (150 keV β emission, $t_{1/2} = 59.4$ days) brachytherapy seeds are the preferred method for localized prostate cancer treatment. However, several drawbacks exist with such a procedure. First, brachytherapy seeds can only be used once and the procedure cannot be repeated

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

within a patient. Second, the long half-life of $^{125}$I may result in radiation-induced tissue damage to surrounding tissues [10]. Also, due to the inability of the low-energy γ rays of $^{125}$I to escape the body as well as the geometry of the seeds, radiation dosimetry estimation is difficult to perform. Additionally, brachytherapy seed preparation involves labeling with $^{125}$I using copper or silver wires in a method that has low yield [11] and more potential radiation exposure, thus a simple and efficient IRT method is needed. Such factors have lead investigators to explore a multitude of therapeutic isotopes that may be suitable for IRT.

Yttrium-90 ($^{90}$Y) (2.28 MeV $\beta^-$ emission, $t_{1/2} = 64$ h) labeled ibritumomab tiuxetan (Zevalin) is the first radioimmunotherapy to receive Food and Drug Administration (FDA) approval and is used for the treatment of relapsed or refractory low-grade, follicular, or transformed B-cell non-Hodgkin's lymphoma (NHL). Although extensive clinical and preclinical studies have been undertaken with different $^{90}$Y molecules, one major drawback exists: It is a pure β em itter and $^{111}$In was used for imaging, biodistribution, and assessing dosimetry [12–14]. However, the estimated dosimetry obtained from $^{111}$In for $^{90}$Y is not accurate enough. Thus, much attention has been directed toward practical application of radiotheranostic radionuclides that have imaging and therapeutic capabilities for more accurate dosimetry calculations [15–21].

Among the rhenium radionuclides, the medium-energy ß emitter $^{186}$Re, with a physical half-life of 3.8 days, makes it a suitable candidate for radiotherapy. However, this reactor-produced $^{186}$Re contains a large amount of carrier, which is the cause of its low reported specific activity (5.92–8.88 GBq/mg, 160–240 mCi/mg Re) [22, 23]. The $^{188}$W/$^{188}$Re generator-produced radionuclide, $^{188}$Re, on the other hand, is carrier free and might offer higher specific activity as in the case of $^{99}$Mo/$^{99m}$Tc (37,000–74,000 MBq/mg; 1000–2000 mCi/mg $^{99m}$Tc), which makes it very convenient for clinical use [24]. $^{188}$Re has good characteristics for imaging and for potential therapeutic use because of its ß energy (2.1 MeV) with tissue penetration of 3.5 mm, its short physical half-life (16.9 h) and its 155-keV γ-ray emission (15%) for dosimetric and imaging purposes. The short physical half-life of $^{188}$Re allows for higher doses compared with long-lived radionuclides. Furthermore, the short half-life reduces the problems of radioactive waste handing and storage. $^{188}$Re is of interest for a variety of therapeutic applications including radioimmunotherapy [25, 26] and use of $^{188}$Re aminex microspheres and colloids for the potential treatment of rheumatoid arthritis of the synovial joints [27, 28] and hepatoma [29, 30]. Other applications that may be pursued include treatment of bone pain with $^{188}$Re-labeled phosphates [31–34]. Recently, an initial feasibility study with $^{188}$Re-hydroxyethylidene diphosphonate ($^{188}$Re-HEDP) using different $^{188}$Re sources demonstrated that application of $^{188}$Re-HEDP is safe and results in pain relief palliation [34]. In addition, dose escalation studied with $^{188}$Re-HEDP in prostate cancer patients showed that a 3.3-GBq (~90-mCi) dose is the maximum tolerated [35].

### 1.3 Selection of Chemistry Chelators for Radiotheranostic Applications

Several chelators have been reported such as $N_4$ (e.g., Cyclam-14, tetraazacyclododecane-1,4,7,10-tetraacetic acid, DOTA), $N_3S$ (e.g., mertiatide, MAG-3), $N_2S_2$ (e.g., ethylene dicysteine, ECD), $NS_3$, $S_4$ (e.g., sulfur colloid), diethylenetriamine pentaacetic acid (DTPA), $O_2S_2$ (e.g., dimercaptol succinic acid, DMSA), and hydrazinenicotinamide (HYNIC) [5, 36–39]. $^{188}$Re is in the same family as $^{99m}$Tc. Thus, $^{99m}$Tc chelates were used for the testing of stability for $^{188}$Re. Among these chelators, DTPA has faster wash out and forms less stable complexes with $^{99m}$Tc. $^{99m}$Tc-HYNIC has been shown to be useful in imaging, but labeling HYNIC with $^{99m}$Tc requires two chemicals, thiphenylphosphine and tricine, which are inconvenient for the kit preparation. The nitrogen and sulfur combination has been shown to be a stable chelator for $^{99m}$Tc-bis-aminoethanethiol tetradentate ligands, also called diaminodithiol compounds, and are known to form very stable Tc(V)O complexes on the basis of efficient binding of the oxotechnetium group to two thiosulfur and two amine nitrogen atoms.

### 1.4 Locoregional Chemoradiotherapy Using Hydrogel

Local administration, coupled with slow release, has demonstrated the ability to deliver effective doses of chemotherapy while significantly reducing commonly associated systemic toxicities [40]. While slow release has favorable characteristics in chemotherapy, it is not ideal when using radionuclides due to leakage of radioactive material and irradiation of nontarget tissues. Current hydrogel technologies are well established for slow-release chemotherapy [41, 42] and are under investigation for radionuclide retention [43–45]. The hydrogel is comprised of two components, a biodegradable polymer such as sodium alginate (SA) and a cross-linker such as calcium chloride or tin chloride, delivered separately from a dual-lumen-type syringe. SA is a hydrophilic gelling polysaccharide extracted from giant brown seaweed that has previously been described as having satisfactory hemocompatibility. Alginates have not been observed to accumulate in any of the major organs, and some evidence for in vivo degradation has even been described [46]. Alginate beads or microspheres can be instantly formed by cross-linking with divalent cations

such as calcium. The reaction is simple, and no toxic material is produced as described below: In addition, SA has a carboxylic group in the repeating unit, which makes it possible to chelate with radiometallic isotopes. In the present study, the use of a hydrogel to deliver combined therapeutic modalities, radiation and chemotherapy, administered locoregionally in tumor-bearing animal models was evaluated.

## 2 MATERIALS AND METHODS

### 2.1 In Situ Formation of Hydrogel

Cisplatin was added to a sodium alginate water solution (5% w/w). For in vitro release assays, the cisplatin-containing solution was added dropwise to a calcium chloride water solution (8% w/w). The hydrogel was formed immediately. The aqueous solution was decanted and the hydrogel was air dried. Preparation of hydrogel for in vivo studies required two injections through a single puncture site in the tumor using a single-lumen syringe. First, sodium alginate was injected intratumorally, followed by injection of calcium chloride. Mild pressure was applied to the injection site to aid in mixing and expedite hydrogel formation. This method was employed with and without the therapeutic components, cisplatin and $^{188}$Re, as dictated by the study. Preparation of $^{188}$Re consisted of elution of radioactivity from a $^{188}$W/$^{188}$Re generator (Oak Ridge National Laboratories, 250 mCi) using 5 mL 0.9% saline. The eluant was passed through a wetted alumina SepPak (Waters) to remove any tungsten-188 breakthrough and reduced in the presence of tin(II) chloride (2 mg) and heat (75°C, 20 min). This yielded reduced $^{188}$Re particles. The $^{188}$Re-containing solution was added dropwise to a calcium chloride water solution (5% w/w) and the hydrogel was formed. For in vivo studies, hydrogel loaded with cisplatin (CDDP) and $^{188}$Re was prepared in situ through a dual-lumen syringe.

### 2.2 Slow-Release Assays

Cisplatin-loaded hydrogel (SA-CDDP) was incubated in phosphate-buffered saline (PBS) in tubes at 37°C. Samples were collected in aliquots at various time intervals for 15 h, and the amount of cisplatin released from the hydrogel was determined by ultraviolet analysis ($\lambda_{max}$ = 230 nm). Cisplatin powder was used as a control.

### 2.3 Cell Viability Assays

Breast tumor cells were obtained from RBA CRL-1747 rat breast cancer cell line (American Type Culture Collection, ATCC< Rockville, MD). This cell line was derived from a tumor induced in Fischer-344 rats by giving an oral dose of 7,12-dimethylbenz[a]anthracene. The cells were cultured in Eagle's medium (MEM) with Earle's balanced salt solution (BSS) (90%) and fetal bovine serum (10%): 50,000 cells were plated into each well of 12-well plates and incubated at 37°C for 48 h to form monolayers. In order to prepare various radioactivity levels for the study, a fixed amount of hydrogel was determined and reacted with varying amounts of $^{188}$Re solution stock in test tubes to allow formation of $^{188}$Re-hydrogel. $^{188}$Re-hydrogel was then added to the cells with varying radioactivity ranging from 25 to 100 μCi/well to determine the relationship between cell viability and increased radiation dose. After 2 h incubation, the cells were harvested and prepared for a protein assay using a modified Lowry's protein assay kit (Sigma). Protein concentration was then determined for each sample using a dual-wavelength spectrophotometer [47, 48]. Hydrogel without $^{188}$Re was used as the control group. Each data point represents an average of three measurements.

### 2.4 In Vitro Radiation Dose Estimates from $^{188}$Re-Hydrogel

To estimate dosimetry emitted from $^{188}$Re-hydrogel, $^{188}$Re-hydrogel (5 mCi) was formulated as previously described in the text. In situ hydrogel with or without streaking forms were performed. Both $^{188}$Re-hydrogel forms were placed in 3-mL vials against X-ray films (MD55 Radiochromic film, Kodak). The films were exposed for 16 h. The color scales were used to estimate radiation dose (Gy) emitted from $^{188}$Re-hydrogel.

### 2.5 Treatment of Tumor-Bearing Animal Models with Hydrogel

The animals were housed in The University of Texas M. D. Anderson Cancer Center facility. All protocols involving animals are approved by the M. D. Anderson Animal Use and Care Committee and adhered to the principles of laboratory animal care. Fischer-344 Rats (150 ± 25 g) (Harlan Sprague–Dawley, Indianapolis, IN) or athymic nude mice were inoculated subcutaneously with rat breast adenocarcinoma cells (13762, $10^6$ cells/rodent) or human prostate tumor cells (PC-3) into the lumber region in legs using 25-gauge needles. The studies were performed 10–12 days after inoculation when tumors were palpable and could be measured. Treatment groups for mammary tumor-bearing rats were designated as control ($n$ = 6), CDDP ($n$ = 5, 5.4 mg/mL, 3 mg/kg body weight), CDDP-hydrogel ($n$ = 5, CDDP equivalent 3 mg/kg body weight), $Na^{188}ReO_4$ ($n$ = 6, 0.5 and 1 mCi/rat), $^{188}$Re-hydrogel ($n$ = 12, 0.5 and 1 mCi/rat), and $^{188}$Re-hydrogel loaded

with CDDP ($n = 3$, 5.4 mg/mL, 3 mg/kg body weight, 0.5–1 mCi/rat). In human prostate tumor-bearing nude mice treated with hydrogel studies, nude mice were inoculated with PC-3 tumor cells and allowed to reach an average tumor volume of 100 $mm^3$ on day 0. Treatment groups for nude mice bearing human prostate tumors were designated as control ($n = 10$), $Na^{188}ReO_4$ ($n = 10$, 1 mCi/mouse), $^{188}$Re-hydrogel ($n = 10$, 1 mCi/mouse), and $^{188}$Re-hydrogel loaded with CDDP ($n = 10$, 5.4 mg/mL, 3 mg/kg body weight, 1 mCi/mouse). Each animal received two injections: sodium alginate (with or without CDDP) followed by calcium chloride (with or without $Na^{188}ReO_4$). All injections were intratumoral and administered through the same puncture site. Slight pressure was applied to the injection site to aid in mixing of the injected chemicals and hydrogel formation. Tumor volume and body weight were recorded daily for 60 days. Tumor volumes were measured as [length ($l$) × width ($w$) × thickness ($h$)]/2. Loss of body weight of 15% was considered a chemical-induced toxic effect. Blood chemical assays [blood urea nitrogen (BUN) and serum creatinine, serum glutamate oxaloacetate transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT)] were performed to detect hydrogel-induced renal or hepatotoxicity. A Student $t$ test was used to compare whether there is a significant difference between groups. To demonstrate the efficacy of hydrogel therapy, tumor specimens from rodents were excised at 48 h postadministration for histopathologic examination.

### 2.6 Assessment of Tumor Growth by Planar Scintigraphy

Scintigraphic images were obtained using an M-camera from Siemens Medical Systems (Hoffman Estates, IL). The camera was equipped with a medium-energy parallel-hole collimator. The field of view is 53.3 cm × 38.7 cm. The intrinsic spatial resolution is 3.2 mm and the pixel size is 19.18 mm (32 × 32, zoom = 1) to 0.187 mm (1024 × 1024, zoom = 3.2).

Animals with injections containing $^{188}$Re were imaged at 24 and 48 h postinjection. To determine tumor growth rate posthydrogel therapy, $^{99m}$Tc-ethylenedicysteine glucosamine ($^{99m}$Tc-EC-DG), a glycolysis marker, was selected for tumor localization. We previously have reported that $^{99m}$Tc-EC-DG is a marker for tumor growth assessment [49]. One rat was selected from each treatment group and was imaged with $^{99m}$Tc-EC-DG (300 μCi/rat, intravenously, 1 h postinjection) on day 9 posttreatment to visualize tumor mass. Tumors were excised and measurements expressed as tumor size (mm) and tumor volume ($mm^3$).

**Figure 1** Alginate hydrogel, loaded with 5.4 mg of CDDP, was placed in a test tube containing PBS and incubated at 37°C for up to 24 h. A 100-μL aliquot was removed at a designated interval. CDDP was quantified by ultraviolet absorbance.

## 3 RESULTS

### 3.1 Slow-Release Assays

Ultraviolet (UV) analysis of 100-μL aliquots showed complete release from the hydrogel within 15 h. The integrity of the hydrogel matrix was maintained through the endpoint of the study. No physical deterioration or degradation was observed. In the absence of hydrogel use, rapid release of CDDP-powder was observed and complete release was achieved within 2.5 h. (Fig. 1).

### 3.2 Cell Viability Assays

After incubation with different doses of $^{188}$Re-hydrogel, protein concentration was determined and showed that cell viability decreased as a function of increasing dose of the radionuclide. The data showed a significant decrease in absorbance in the 50-μCi group as compared to controls (Fig. 2). The 100-μCi group had >80% decrease in absorbance and may serve as a marker for the dose needed to kill tumor cells in vivo.

### 3.3 In Vitro Radiation Dose Estimates from $^{188}$Re Hydrogel

$^{188}$Re-hydrogel was placed in a 3-mL vial against X-ray films for 16 h as shown in Figure 3. Treatment of $^{188}$Re-hydrogel with or without streaking forms was performed. The color scales showed estimate radiation dose (Gy) emitted from $^{188}$Re-hydrogel (Fig. 4). Both forms had homogenous emission. The dose density in streaking form was less than that with hydrogel without streaking form.

### 3.4 Treatment of Tumor-Bearing Animal Models with Hydrogel

Animals were successfully injected with sodium alginate and $CaCl_2$ (in the presence of CDDP or $^{188}$Re) using the same injection site for each component. A resulting subcutaneous gel-like ball was formed near the injection site and designated that cross-linking had occurred and was also used as a marker to demonstrate that the hydrogel was intact. In mammary tumor-bearing rats treated with hydrogel studies, repeated measurements of tumor volume showed a clear delay in tumor growth in the $^{188}$Re-hydrogel group as compared to $^{188}$Re and control groups (Fig. 5), prolonging survival more than 2 times that of untreated rats. Low-dose $^{188}$Re-hydrogel (0.5 mCi) loaded with CDDP showed more anticancer effects than $^{188}$Re-hydrogel alone (Fig. 5). Rats given higher doses (1 mCi/rat) of $^{188}$Re/$^{188}$Re-hydrogel showed increased delay in tumor growth (Fig. 6) and those treated with CDDP-hydrogel demonstrated complete remission of tumors (Fig. 7A) while the untreated group experienced rapid increase in tumor size within 4 days, leading to euthanization due to excessive tumor burden (Fig. 7B). No marked difference in tumor volume was observed between $^{188}$Re-hydrogel (0.5 mCi) loaded with CDDP and CDDP-hydrogel (Fig. 7A). This effect might be due to the dose of $^{188}$Re used. Assessment of renal toxicity in CDDP-hydrogel-treated rats was shown to be minimal as demonstrated by minor variations in BUN and serum creatinine levels following treatment (Fig. 8). In nude mice bearing human prostate tumors administered with $^{188}$Re, $^{188}$Re-hydrogel, and $^{188}$Re-CDDP-hydrogel, the $^{188}$Re-CDDP-hydrogel showed more pronounced anticancer effect than free $^{188}$Re or gel alone (Fig. 9). Pathological stating of prostate tumor tissue post$^{188}$Re-CDDP-hydrogel showed cell apoptosis at 48 h (Fig. 10).

**Figure 2** Increasing radioactivity was added to each well and the cytotoxicity was assessed using a protein assay kit to determine UV absorbance. $*p < 0.05$, $t$ test compared to control group.

### 3.5 Assessment of Tumor Growth by Planar Scintigraphy

One of the groups treated with $^{188}$Re-hydrogel was monitored with planar scintigraphic imaging (Fig. 11). Images taken at 24 and 48 h postinjection of $^{188}$Re showed very poor retention of the radionuclide at the

**Figure 3** Hydrogel with or without streaking forms were performed. Hydrogel was placed in a 3-mL vial against X-ray films (MD55 Radiochromic film, Kodak) for 16 h.

**Figure 4** $^{188}$Re-hydrogel with or without streaking forms were performed. The color scales showed estimate radiation dose (Gy) emitted from $^{188}$Re-hydrogel. Both forms had homogenous emission. The dose density in streaking form was less than that hydrogel without streaking form.

**Figure 5** Mammary tumor-bearing rats were randomized into three groups and injected with $^{188}$Re and $^{188}$Re-hydrogel (single injection, intratumorally, 0.5 mCi/rat). Tumor volume was measured and compared to the untreated group. $p < 0.05$, $t$ test: *compared to treated groups; **compared to $^{188}$Re and $^{188}$Re-hydrogel.

**Figure 6** Mammary tumor-bearing rats were treated with $^{188}$Re and $^{188}$Re-hydrogel (single injection, intratumorally, 1 mCi/rat) and tumor volume was monitored for up to 16 days posttreatment. Rats given higher doses (1 mCi/rat) of $^{188}$Re-hydrogel showed increased delay in tumor growth. *$p < 0.05$, $t$ test compared to $^{188}$Re.

injection site, with diffusion throughout the whole body and localization in the stomach of one rat. Imaging of the $^{188}$Re-hydrogel group demonstrated that the hydrogel can effectively trap the radionuclide at 48 h postinjection. No thyroid or stomach uptake was observed, signifying the absence of free $^{188}$Re from systemic circulation. Prior to sacrificing of the animals, imaging with $^{99m}$Tc-EC-DG allowed for clear visualization of tumors and qualitatively demonstrated significant differences in tumor size of $^{188}$Re and $^{188}$Re-hydrogel samples, respectively, based on count density in the tumor region (Fig. 12). Excision of the tumors and measurement of tumor volume showed correlation between count density and tumor volume.

## 4 DISCUSSION

Clinical use of ionizing radiation commonly involves dealing with external sources such as X-ray, proton, and neutron beams. Internal use of radiation is performed using brachytherapy, which takes advantage of the close

**Figure 7** (A) Mammary tumor-bearing rats were treated with CDDP-hydrogel (single injection, intratumorally, 3 mg/kg) and $^{188}$Re-CDDP-hydrogel (single injection, intratumorally, 0.5 mCi) and tumor volume was monitored until no longer palpable. (B) Tumor volume of untreated mammary tumor-bearing rats was monitored until tumor burden became too large and animals were euthanized. $*p < 0.05$, *t* test compared to day 2.

**Figure 8** Effect of CDDP-hydrogel on renal function of treated rats was assessed by monitoring BUN and serum creatinine levels for 16 days posttreatment.

proximity of the radioactive seeds to the tumor and delivers a predetermined radioactive dose for treatment.

Brachytherapy is an attractive treatment option for prostate cancer since the seeds are deposited intratumorally and spare surrounding healthy tissues from damage. $^{125}$I (half-life = 59.4 days) seeds are the preferred source but palladium-103 ($^{103}$Pd, half-life = 16.9 days) seeds are in use as well. Researchers are now seeking to expand the use of brachytherapy to multiple tumor types such as head and neck, breast and lung, among others. Some drawbacks, however, exist when using brachytherapy for treatment. First, brachytherapy seeds are nonbiodegradable and will remain in the area where they are injected permanently. Therefore, a patient that already received a seed implant is very unlikely to receive another one and must seek alternative treatment should tumor recurrence occur. Second, although these seeds are radioactive, they lack the ability to incorporate chemotherapy into their existing application.

While it has been shown that combined chemoradiation therapy has synergistic effects in various tumor types, such applications are not clinically available with brachytherapy but may be feasible as suggested by the hydrogel findings presented in this chapter. Figure 9 shows a comparison of some key differences between hydrogel and brachytherapy. The hydrogel is composed of a biodegradable, hemocompatible polymer that is virtually nontoxic. This polymer, once cross-linked with calcium chloride, forms with a 'gel-like' consistency and can be prepared in multiple configurations (thin tracks, globular, etc.). It must be noted that administration of the gel into the tumor will have an adverse effect on tumor volume, initially due to an increase in interstitial pressure and general enlargement of the area, followed by reduction in volume resulting from the therapeutic modality delivered (Fig. 7A). Though our in vivo imaging studies have not reached the necessary degradation time for alginate hydrogel, the data indicates that $^{188}$Re-gel is stable and localized at least up to 4 days (data not shown). Others have reported that 40% of the gel weight dissolved after 15 weeks, suggesting that degradation can occur in time frames ranging from 3 weeks to more than 4 months by simply varying the number of covalent and ionic cross-links [50]. The longevity with which the hydrogel remains intact in vivo coincides well with the selection of $^{188}$Re since, generally, >99% of a radionuclide is decayed after 10 half-lives, which is 7.1 days in the case of $^{188}$Re. This ensures that by the time breakdown of the hydrogel occurs no radioactivity remains and toxicity to surrounding tissue will be negligible. Additionally, the loading dose of the hydrogel can be varied based on the needs of the patient, shape

**Figure 9** Nude mice were inoculated with PC-3 tumor cells and allowed to reach an average tumor volume of 100 $mm^3$ on day 0. The mice were injected [intratumoral (i.t.)] with $^{188}$Re, $^{188}$Re-hydrogel, and $^{188}$Re-cisplatin (CDDP)-hydrogel (1 mCi, 250 μg). The tumor volume was monitored until tumor burdens became excessive. $^{188}$Re-CDDP-hydrogel showed more pronounced anticancer effect than free $^{188}$Re or gel alone.

**Figure 10** H and E staining of prostate tumor tissue post-188Re-hydrogel and 188Re-CDDP-hydrogel showed cell apoptosis at 48 h (40×).

and location of the tumor, susceptibility of surrounding healthy tissue to radiation, and planned number of treatments. Increasing amounts of hydrogel and accompanying radioactivity can be delivered to certain sites as required based on delivery from a dual-lumen syringe, which can be administered under computed tomography (CT) or ultrasound (US) guidance using an automated step motor to ensure accurate and reproducible dose distribution. Ongoing studies have shown promising data using radiochromic film (not shown) for

**Figure 11** Rats were injected with $Na^{188}ReO4$ (A) and $^{188}$Re-hydrogel (B) (1 mCi/rat, i.t.) in the hind limb and imaged at 24 and 48 h postinjection. Medium-energy collimator was used and the images demonstrate that $^{188}$Re-hydrogel provides locoregional radionuclide therapy and prevents whole-body distribution. Injection site shown by arrow.

**Figure 12** Mammary tumor-bearing rats treated with $Na^{188}ReO_4$ (left) and $^{188}$Re-hydrogel (right) were imaged with 99mTc-EC-DG (a glycolysis marker, at 1 h) on day 9 posttreatment to visualize tumor mass. Tumors were excised and measurements are shown as tumor size (mm) and tumor volume ($mm^3$).

determining dosimetry and absorbed dose spatially, and may serve as a powerful tool in treatment planning.

In an attempt to incorporate well-known slow-release methodologies for drug delivery with radiotherapy, we developed a hydrogel that plays two roles in cancer treatment: (1) slow release of chemotherapeutic agents and (2) trapping of therapeutic radionuclides. While many hydrogels exist with similar polymeric composition and drug delivery capability, the uniqueness of this hydrogel lies in the chemical properties associated with the cross-linking agent calcium chloride. Calcium chloride acts bifunctionally in this system: forming a complex with $^{188}$Re and cross-linking with sodium alginate. This leads to gel formation and slow release of CDDP coupled with trapping of $^{188}$Re at the site of injection, which can be monitored by imaging. $^{188}$Re was chosen for this particular study because of its therapeutic potential, however, different contrast materials such at gadolinium-containing compounds for MRI, or iodine-containing compounds for CT could also be incorporated into the hydrogel framework and serve as a high-resolution guide to demonstrate where the therapy is actually being delivered, as well as how long the hydrogel is able to maintain its integrity in vivo.

In summary, we have demonstrated that in situ hydrogel can be used for local-regional delivery of chemotherapy and radiotherapy while reducing associated toxicities found with traditional delivery methods. The findings demonstrate the potential uses of image-guided therapy in cancer treatment.

# RNAi-MEDIATED THERAPEUTICS

Núria Morral and Scott R. Witting

*Department of Medical and Molecular Genetics and Center for Diabetes Research, Indiana University School of Medicine, Indianapolis, Indiana*

## 1 INTRODUCTION

Ribonucleic acid interference (RNAi) is the phenomenon by which small noncoding RNAs suppress the expression of a gene. In the early 1990s, experiments to block protein expression using antisense technology [i.e., RNA complementary to the target messenger RNA (mRNA)] indicated that introduction of the sense strand could also promote silencing [45, 55], suggesting that the silencing effect was the result of an independent mechanism. Later on, Fire and collaborators observed that in *Caenorhabditis elegans*, administration of double-stranded RNA (dsRNA) was at least two orders of magnitude more potent than the antisense or sense strands alone [46]. Furthermore, the interference effect spread from the tissue in which the dsRNA was injected to other tissues, and it was passed from the parental animal to the next generation through the germ line [46].

This seminal work triggered interest in determining whether RNA interference would be observed in other organisms. Present in most eukaryotes, including plants, *Neurospora*, *Drosophila*, and mammals [42, 57, 122, 140, 167], it is now clear this is a universal mechanism used to modulate gene expression. RNAi is triggered by dsRNA of variable lengths, which are processed to short RNA duplexes, approximately 21–28 nucleotides (nt) long. The first RNA silencing mechanisms were discovered as part of an antiviral response believed to protect organisms from viral infection. It was later discovered that cells have the capacity to synthesize small RNAs known as microRNA (miRNA), which regulate hundreds of genes, coordinating complex developmental as well as physiological responses. Based on the fact that miRNA molecules modulate gene expression in all mammalian tissues, RNAi is being exploited as a system for the treatment of human diseases as well as to study gene function.

## 2 MECHANISMS OF GENE SILENCING

### 2.1 MicroRNA

MicroRNAs (miRNAs) are small RNA molecules that regulate expression of genes involved in cellular metabolic pathways, development, cell differentiation, proliferation, and death [14, 22, 78, 138, 185]. It has been estimated that in eukaryotes, approximately 0.5–1% of predicted genes encode a microRNA, which in humans, regulates 30% of genes at an average of 200 genes per miRNA [86, 160]. MicroRNAs are tissue specific and differentially expressed during development [5, 80]. Although the gene targets of the majority of miRNA are still unknown, some have been determined. One such example is miR-122, which is abundantly expressed in liver, where it regulates a large number of cholesterol synthesis genes [78]. Another example is brain-specific miR-134, which negatively modulates the size of dendritic spines [148]. MicroRNAs have become targets for the treatment of cancer, as many are dysregulated in

**Figure 1** RNAi machinery. In the miRNA pathway (top left), pri-miRNA generated by RNA polymerase II are processed to pre-miRNA by Drosha-DGCR8, and transported to the cytoplasm by exportin-5. Dicer-TRBP-PACT cleaves the loop sequence, generating ~22 nt sequences with 2-nt 3′ overhangs. RISC-AGO2 unwinds the dsRNA molecule and selects one strand for degradation while the other is used to direct silencing of the target mRNA. In animal cells, the majority of the mRNA is translationally repressed rather than degraded, although deadenylation and subsequent 5′ decapping, exposing the mRNA to exonuclease degradation, have also been observed. Expression of shRNA from a viral vector (top right) results in synthesis of molecules that enter the RNAi pathway at the exportin-5 level. shRNA are typically designed to completely match the mRNA target sequence, thereby inducing mRNA cleavage by AGO2. Chemically synthesized siRNA do not require Dicer activity and are directly processed by the RISC complex, triggering mRNA degradation. DG, DiGeorge syndrome critical region 8; PA, protein activator of PKR (PACT); TRBP, TAR RNA-binding protein; RISC, RNA-induced silencing complex; AGO2, endonuclease Argonaute 2.

oncogenic processes. For example, let-7 is a tumor-supressor miRNA, regulating the HMGA2 oncogene [85]. Its expression in breast cancer cell lines reduced cell proliferation [188].

MicroRNAs are transcribed by RNA polymerase II [18, 84] (and polymerase III to a lower extent [10]) as long primary transcripts (pri-miRNA). Pri-miRNA are cleaved by the microprocessor complex [34, 51], composed of the ribonuclease III Drosha and the dsRNA-binding protein DiGeorge syndrome critical region 8 (DGCR8), to generate precursor structures known as pre-miRNA (Fig. 1). Pre-miRNA are stem-loop molecules approximately 70-nt long, with a 5′ phosphate group and a 2-nt 3′ overhang [83]. Pre-miRNAs are

bound by karyopherin exportin-5 and transported out of the nucleus [96, 187]. In the cytoplasm, pre-miRNA are cleaved by the RNase III enzyme Dicer, which removes the loop sequence, leaving ~22-nt dsRNA molecules with 2-nt overhangs in the 3′ end of each of the two strands. This structure is recognized by the RNA-induced silencing complex (RISC), which selects one of the two strands for degradation (referred to as the passenger strand) and loads the guide strand, which is then used to bind the mRNA with a complementary sequence [50, 99, 134]. The core subunit of RISC is Argonaute 2, an endonuclease that is responsible for binding the miRNA and cleaving the target mRNA. The level of complementarity between the guide strand and the mRNA sequence determines whether protein synthesis will be inhibited or the mRNA will be degraded. Binding to the target mRNA with only partial homology blocks protein translation without inducing cleavage of the mRNA, while perfect or nearly perfect complementarity induces mRNA degradation. In animals, the guide strand usually binds to the 3′ untranslated region (UTR) of mRNAs imperfectly, resulting in protein translation inhibition and exonucleolytic mRNA degradation in cytoplasmic compartments known as processing bodies (P bodies) [94, 130].

Multiple studies have provided evidence that the 5′ region of miRNA is critical for gene silencing. In particular, nucleotide positions 2–7 or 2–8 from the 5′ end ("seed" region) (Fig. 2) are the most conserved among metazoan miRNAs [87], playing a key role in determining target specificity. Alteration of a nucleotide in these positions results in a significant reduction of silencing efficacy.

**Figure 2** Examples of siRNA modifications/delivery systems. (A) Unmodified siRNA; (B) modified nucleotides in the 2′ position of the pentose sugar stabilizes the dsRNA in vivo, making it less susceptible to be degraded by nucleases. In the example, 2′-*O*-methyl modifications have been incorporated. The optimal number of nucleotides that are modified needs to be tested by the investigator. (C) Cholesterol-conjugated siRNA provides a way to enhance uptake by tissues. (D) Protamine-complexed siRNA. An antibody fragment that recognizes a cell-specific receptor can be incorporated for targeted delivery.

## 2.2 siRNA and shRNA

The discovery of RNAi as a cellular pathway to modulate expression of endogenous genes was exploited to generate small interfering RNA (siRNA) to silence a gene of interest. siRNAs are designed to perfectly match the target sequence. The sense and antisense strands are chemically synthesized and after annealing, a double-stranded RNA with 2-nt 3′ overhangs is generated. Thus, the structure is similar to that of miRNA generated by Dicer (Fig. 1). Upon entering the cell, siRNA molecules are processed by RISC in the cytoplasm, which cleaves the target mRNA between nucleotides 10 and 11 of the guide strand, relative to its 5′ end [43].

siRNA can block gene expression for a few days, and readministration is necessary for a sustained silencing effect. Alternatively, short hairpin RNA (shRNA) can be used to provide a continuous source of silencing molecules. To generate shRNA, expression cassettes are engineered using RNA polymerase II or RNA polymerase III promoters. The sequences are usually designed for perfect complementarity to the mRNA. The shRNA is transcribed in the nucleus as a linear molecule that folds to generate a stem of approximately 21 nt, connected with a loop sequence of variable length. Thus, shRNAs have a similar structure to pre-miRNA and are transported to the cytoplasm similarly to pre-miRNA, that is, through the exportin-5 pathway. Once in the cytoplasm, shRNAs are processed by Dicer and subsequently by RISC, inducing endonucleolytic degradation of the target mRNA, as described for siRNA. shRNA expression cassettes can be delivered to cells

using plasmids or viral vectors such as lentivirus, adenovirus, or adeno-associated virus (AAV).

## 3 OFF-TARGET AND UNSPECIFIC EFFECTS

### 3.1 Off-Target Effects

An unwanted consequence of RNAi is the silencing of genes other than the one intended to target (known as off-target effects). High concentrations of siRNA lead to dose-dependent nonspecific gene downregulation patterns [129, 151] and toxicity [44]. These effects are sequence dependent in addition to concentration dependent. As little as 11 consecutive nucleotides matching an mRNA can result in cleavage [67]. In a recent study no correlation was found between the extent of target silencing and the number of off-target genes affected [67]. The UGGC motif, in particular, was found to be toxic and, therefore, should be avoided in any siRNA or shRNA construct [44]. The seed region of the RISC-entering strand should not overlap with the 3′ UTR of untargeted mRNA or silencing may take place [9]. In a similar manner, RNAi can block translation with as little as three to four mismatches (G-U "wobble") in the coding regions of mRNA [144]. Indeed, this mechanism is used to silence genes via the endogenous miRNA processing pathway in animals [73]. Matches in the seed region are more critical when using endogenously expressed shRNA as siRNA can be chemically modified with a 2′-*O*-methyl substitution at position 2 of the ribose in the guide strand to avoid off-target effects [68].

### 3.2 Unspecific Effects

In mammalian cells, a defense mechanism against viral infections is the recognition of foreign single-stranded (SS) or double-stranded RNA. Most cell types respond to the presence of foreign RNA by activating at least three RNA-binding proteins: dsRNA-dependent protein kinase (PKR), 2′,5′-oligoadenylate synthetases (OASs), and Toll-like receptors (TLRs) [157, 158]. The presence of dsRNA in the cell induces PKR autophosphorylation and subsequent phosphorylation of its substrates, resulting in general protein translation inhibition [162]. In addition, PKR activation initiates signal transduction events resulting in the production of interferons (IFNs), resulting in upregulation of interferon-stimulated genes (ISG), mediators of proapoptotic events. Interferons represent part of the innate immune system and act as a first line of defense against infections. Production of these cytokines is induced by pathogens such as bacteria, viruses, and fungi, and they function in a paracrine manner to protect cells from infection [7]. Two main families of interferons have been described: type I (IFN-α/β) and type II (IFN-γ). Type I interferons are induced by most cell types, in addition to plasmacytoid dendritic cells, leukocytes, and fibroblasts [82], while type II interferons are secreted by T lymphocytes and natural killer cells [162].

A second RNA sensor is 2′,5′-oligoadenylate synthetase (OAS), which is activated by dsRNA, inducing the conversion of adenosine 5′-triphosphate (ATP) into short 2′,5′-oligoadenylates that bind to and activate RNase L. This leads to cleavage of cellular and viral RNA, resulting in inhibition of protein translation [89, 162]. The third RNA sensor involves Toll-like receptors, signaling proteins expressed in the cell membrane or in intracellular membranes [152]. Each of the 11 members of this family responds to a specific ligand. Detection of foreign RNAs in the endosomes/plasma membrane are mediated by Toll-like receptor-3 (TLR3) [4, 71] and Toll-like receptor-7 (TLR7), and the downstream effect is the activation of IFNα/β production [38]. Generation of the signaling cascade leading to IFN expression can be mediated by other cytosolic ssRNA/dsRNA sensors, including retinoic acid inducible gene 1 (RIG1) and melanoma differentiation associated gene-5 (MDA-5), which detect foreign RNAs in the cytosol and initiate a signal to express IFNs [106].

Initial studies using small interfering RNA intermediates of 21–23 nt were found to bypass these responses [42] and were used by multiple investigators to study the effects of inhibiting gene expression in cell culture [6, 16, 42, 164] as well as in vivo [62, 76, 88, 100, 103, 181]. As a result of the increasing number of research applications using RNA interference, it has recently become clear that siRNA molecules have the capacity to induce unspecific effects. Indeed, multiple investigators have observed stimulation of interferon-induced genes using both siRNA [70, 71, 156] and shRNA [15, 47, 71, 127]. This discrepancy is likely because the early reports centered on PKR and predated the characterization of other important RNA-sensing proteins (i.e., RIG-1, MDA-5, TLRs) [48]. Although some controversy exists on whether or not siRNA/shRNA activate the complete interferon pathway [147], it is apparent that some downstream effectors/genes are shared [129]. Sequence-dependent mechanisms of interferon response induction exist. For example, activation of TLR7 in plasmacytoid dendritic cells involves a GUCCUUCAA motif [63]. A similar study found the UGUGU motif to be a potent inducer of the interferon response, although the role of TLR7 was not explored [70]. Therefore, both motifs should be avoided when using shRNA in vivo. With siRNA, it was found that incorporating 2′-*O*-methyl (2′O-Me) uridine or guanosine nucleosides into the antisense strand prevented an interferon response [69].

A major limitation in the use of shRNA-based vectors in vivo will be the potential for interferon response induction. When using helper-dependent adenovirus, we have found that expression of shRNA in liver requires careful titration of the dose to avoid the interferon response [177]. In general, in vivo studies using shRNA should include a pilot study to determine optimum vector doses in the tissue of interest that lead to the highest silencing without interferon induction. Analysis of the target tissue can be performed by examining the tissue histologically and looking for signs of inflammation and apoptosis. Also, the levels of known interferon-stimulated genes, such as OAS [157] and interferon-stimulated gene 20 (ISG20) [115], can be evaluated by Northern blot or quantitative real-time PCR.

Another issue specific to the use of shRNA constructs involves the protein exportin-5, which mediates the transport of unprocessed miRNA and shRNA out of the nucleus [187]. This pathway can become saturated when high levels of shRNA are expressed leading to cellular toxicity [186]. A study performed in mice found that saturation of exportin-5 was likely the cause of severe morbidity and mortality when shRNA was expressed in the liver. Longer hairpins [over 19 base pairs (bp)] tended to be more toxic [53]. To avoid this problem, the optimal dose of vector needs to be determined to reach efficient target silencing in the absence of unspecific events. Choosing the construct with the highest efficacy in vitro will facilitate reducing the dose. Alternatively, shRNA expression could be controlled with an inducible promoter, as discussed below. Monitoring the target tissue for levels of at least two abundantly expressed endogenous miRNAs (such as miR122 and let7a in liver), will help determine whether the amount of shRNA expressed results in exportin-5 saturation [177].

## 4 CHEMICALLY SYNTHESIZED SMALL INTERFERING RNA (siRNA)

### 4.1 siRNA Design

Conventionally designed siRNA are 21 nt with 2-nt 3′ overhangs. The design of the siRNA starts by selecting a suitable 19- to 21-nt sequence from the mRNA. The target transcript sequence can be obtained from the Entrez database provided by the National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov/Entrez). The open reading frame (ORF) is used to select sequences that will be targeted by siRNA. If the ORF is short, the 5′ and 3′ untranslated regions can also be included. Algorithms are currently available to choose a sequence that can potentially induce efficient gene silencing, and several companies (Ambion, Dharmacon, GenScript Corporation, Invitrogen) offer them online for custom design of optimal sequences. For the beginner, these are very useful tools, as the user can introduce the target mRNA sequence, and the system returns selected sequences based on their algorithms.

Multiple factors affect the potency of a silencing construct, including siRNA length, duplex stability, sequence asymmetry of the overhangs, as well as nucleotide composition in specific positions of the siRNA, with end stability being the most important feature [8, 128]. RISC preferentially loads the strand that displays the less stable 5′ end in the duplex [66]. Once the sequence to be targeted is selected, it is important to look for possible homologies to mRNAs other than the target. This is typically done using the Basic Local Alignment Search Tool (BLAST) (www.ncbi.nlm.nih.gov/blast/Blast.cgi), which compares a query sequence with a gene database. Sequences with the least number of matching nucleotides in genes are potentially less susceptible to give rise to off-target effects. Table 1 shows the considerations to be taken into account to generate effective siRNAs, based on current knowledge of critical elements that influence siRNA performance. For detailed information on each of the aspects affecting siRNA potency, an excellent protocol has been recently published by Birmingham and colleagues [8].

**TABLE 1 Considerations to Generate Potent siRNA**

| |
|---|
| Select all possible 19-nt to 21-nt sequences that are not located in areas with known polymorphisms. |
| Remove sequences that contain stretches with >5 single nucleotides, as these may lead to increased level of off-targeting [8]. |
| Remove sequences with a GC content > 64% (which affects helicase activity to unwind the dsRNA), or lower than 30% [8, 128]. |
| Remove sequences that may form internal hairpins (which may decrease silencing efficacy) and palindromes [126]. |
| Select sequences that have a thermodynamically favorable composition in the antisense strand. The strand with the less stable 5′ ends (usually A+U enriched) will be loaded into RISC [66, 72, 149]. |
| To enforce specificity, after a BLAST analysis, select sequences with at least three mismatches in positions 2–19 to undesired mRNAs. Avoid sequences with an antisense strand seed region that perfectly matches the 3′ UTR of mRNA. A Web-based algorithm to identify mRNAs with seed matches to the RNAi sequence is available from Dharmacon (http://www.dharmacon.com/seedlocator/default.aspx) [92, 128]. |
| Remove sequences with known toxic motifs that can trigger unspecific effects, such as 5′-GUCCUUCAA-3′ [63]. |

After several siRNA sequences have been identified, the investigator needs to test a minimum of four to determine their potency, as well as test for the presence of unspecific effects such as activation of the interferon response. This can be done by transfecting the siRNA in a cell line known to express the target gene. In some instances, though, this is not possible, as some cell lines are very difficult to transfect. A couple of approaches can be used in this case. One is to generate a construct consisting of the target sequence fused to the mRNA of a reporter protein, such as luciferase. This fusion construct can be co-transfected into HEK293 cells (which are easily transfected using commercially available reagents), together with the target-specific siRNA and a plasmid containing a control gene for normalization. The degree of luciferase activity allows determining the level of knock-down. Alternatively, it is also possible to generate an expression cassette with the comphementary DNA (cDNA) of the target gene, and quantify its mRNA or protein upon co-transfection with the siRNA [177]. Finally, the psiCHECK system (Promega, Madison, WI) can be used to not only test efficacy but also RISC selection of the sense and antisense strand. High levels of sense strand loading may decrease efficacy and, more importantly, lead to potential unspecific effects.

### 4.2 siRNA Stability

One of the major hurdles to effective RNAi is the limited stability of the siRNA molecules. In vitro, chemically synthesized, unmodified dsRNA have a half-life of 3–5 min [110]. These are suitable for most applications because cells quickly internalize the molecules. However, upon systemic injection into animals, nucleic acids are rapidly degraded by endo- and exonucleases. This limitation makes siRNA very ineffective for therapeutic purposes. Thus, the real challenge when it comes to a clinically relevant siRNA drug, is the delivery and stability of the siRNA molecule, rather than its efficacy at knocking down its target. Extensive research has been conducted to increase the stability of siRNAs so that they circulate for a longer time in blood and, therefore, allow for a more potent effect.

As described above, once the siRNA has entered a cell, unwinding by helicase activity takes place, and the sense or passenger strand is degraded while the antisense or guide strand is incorporated into RISC, mediating the silencing effect. The siRNA is designed such that the antisense strand is favored over the sense strand for loading onto RISC. It has been shown that single-stranded RNAs are less efficacious at silencing than dsRNA. Thus, the sense strand seems to provide stability to the molecule, making it less susceptible to degradation, and providing a template for degradation by RISC, which allows selection of the antisense strand to effect gene silencing. Because the process of mRNA recognition and cleavage is highly specific compared to strand selection for uploading into the RISC complex, it is more feasible to introduce changes in the sense strand than in the antisense strand. The position along the 21-nt sequence that is modified is also important, and perturbing certain nucleotides results in loss of functionality.

The starting point for chemical modifications has been incorporating backbone modifications (Fig. 2). For example, a phosphorothioate linkage provides exonuclease protection while retaining potency [25, 56]. A second possible modification is changing the functional group in position 2′ of the sugar ring. These modifications are introduced to protect the siRNA from endonucleases and are more likely to interfere with gene silencing efficacy. In one study, inclusion of 2′-fluoro substitutions protected the molecule against endonuclease activity and increased its stability in serum but did not result in a prolonged silencing effect [81]. In a related study, addition of 2′-fluoro substitutions in all pyrimidines (sense and antisense strands) in addition to other substitutions resulted in 900-fold increase in stability and higher potency in a mouse model of hepatitis B virus replication [110]. Addition of a 2′-*O*-methyl group in a limited number of nucleotides was also well tolerated and increased the performance of the siRNA [30, 61]. Other modifications that are possible in the 2′ position include locked nucleic acid (LNA), 2′-*O*-(2,4-dinitrophenyl) (2-DNP), 2′-deoxy, and 2′-*O*-(2-methoxylethyl) (2′-*O*-MOE), which are more extensively described in recent reviews [1, 192]. Progress in this area is slow because after testing in cells, it is necessary to try the modified siRNA in animal models in order to generate a therapeutic drug.

### 4.3 siRNA Delivery

Delivery of the siRNA drug remains the most challenging aspect of siRNA therapeutics. When systemically administered, siRNAs accumulate in blood, liver, lung, kidney, spleen, and intestine [12, 173]. The mechanism used by cells to take siRNA is not yet clear, but it is possible that it occurs through non-receptor-mediated endocytosis. Reaching the appropriate tissue can be accomplished by conjugating the siRNA molecule to specific ligands. The route of delivery is another important factor.

***Natural Ligands, Proteins, and Aptamers*** As mentioned above, naked siRNAs are highly unstable in blood and are degraded quickly by nucleases. siRNA can be conjugated with molecules that protect them

from degradation and at the same time allow targeted delivery. In general, terminal modifications affecting the 3′ end of the sense or antisense strand are well tolerated and do not interfere with the ability of the antisense strand to effect target mRNA degradation. Modifications in the 5′ end of the antisense strand are not well tolerated and usually reduce the silencing activity, while modifications in the 5′ of the sense strand do not affect siRNA activity. The most widely used siRNA conjugates used include natural ligands, peptides, and aptamers (RNA molecules that can bind specific receptors) [1].

It has been shown in mice that conjugation of siRNA to cholesterol to target ApoB is a feasible strategy to reduce its mRNA by 55% in the liver and 70% in the jejunum [161], resulting in a drop of plasma cholesterol of approximately 70%. Conjugation to cholesterol provided enhanced pharmacokinetics, presumably through binding to serum proteins [161]. Tissue biodistribution included liver, heart, kidney, adipose, and lung [161]. Wolfrum and colleagues [179] have shown that conjugation of siRNA to cholesterol as well as other lipophilic compounds, such as bile acids or fatty acids, results in uptake by cells expressing specific lipoprotein receptors. siRNA conjugated with high-density lipoproteins (HDL) were taken up preferentially by liver, kidney, adrenal gland, ovary, and intestine, in an SR-BI receptor-dependent manner, while low-density lipoproteins (LDL)-conjugated siRNA were mainly taken up by the liver, through the LDL receptor [179]. Interestingly, the uptake was independent from lipoprotein endocytosis, suggesting a model where the particles bind to the receptors, and uptake is dependent on a distinct transmembrane transporter [179].

The tolerance of the sense strand for chemical modifications has been exploited to conjugate siRNA to membrane permeant peptides, such as penetratin or transportan [112]. These conjugates reduce transgene expression in multiple cell lines. RNA aptamers have been used to direct cellular uptake in vitro and in animal models. For example, prostate cancer cells express high levels of prostate-specific membrane antigen (PSMA), a cell surface receptor. McNamara and colleagues showed that aptamer-conjugated siRNA to silence polo-like kinase 1 (PLK1) significantly reduced tumor size in a PMSA expression-dependent manner in a xenograft model of prostate cancer [105].

***Cationic Delivery Systems*** Cationic lipids, polymers, and dendrimers (branched polymers) have been used as vectors for siRNA delivery to tissues (also referred to as lipoplexes, polyplexes, and dendriplexes, respectively). These positively charged molecules facilitate complex formation with nucleic acids and interaction with the negatively charged cell membrane. Examples of cationic lipids that are commercially available are Lipofectamine (Invitrogen), Oligofectamine (Invitrogen), or TransIT TKO (Mirus Bio Corporation). Polymers used include polyethyleneimine (PEI), Arg-Gly-Asp (RGD) peptide, and protamine. siRNA uptake occurs through endosome formation. To facilitate endosomal escape, PEI or pH-sensitive peptides such as poly-histidine-lysine, have been included in the complex to facilitate endosomal disruption and release of the siRNA complex into the cytoplasm [2]. Complexes can be designed to include an antibody or other ligand for targeting to a specific tissue (Fig. 2). For example, a heavy-chain antibody fragment (Fab) fused to protamine has been complexed to siRNA to selectively target cells expressing human immunodeficiency virus (HIV-1) envelope protein gp160 [159]. In a mouse model of melanoma, a cocktail of Fab-conjugated siRNA against c-myc, MDM2, and vascular endothelial growth factor resulted in reduced tumor size only in cells expressing the glycoprotein gp160 [159].

The optimal delivery system should be one that results in highest RNAi efficacy at the lowest dose and does not induce off-target or unspecific effects. In this regard, a few studies have shown by microarray analysis that the transfection reagent per se can induce alterations in gene expression [119, 120]. For example, cationic lipids can generate such responses, in addition to enhancing immune responses triggered by siRNA [97]. Thus, when planning on using a delivery system, caution needs to be taken to avoid these potential unspecific events.

## 5 EXPRESSION OF SHORT HAIRPIN RNA (shRNA) CONSTRUCTS

### 5.1 Hairpin Design

Two possible approaches can be used to express shRNA. The first one consists of generating a structure that has a stem with complete homology to the target sequence [16, 121]. The second involves a longer structure, with the features of a microRNA [104, 155, 190] (Fig. 3). There is some discrepancy as to which system is more efficacious at knocking down expression [90, 155, 163]. Hence, choosing one over the other is a matter of personal preference.

A successful shRNA design should contain many of the features discussed in the siRNA section. These include avoidance of known toxic motifs and BLAST analysis to confirm target specificity. However, recent studies have found siRNA algorithms are only modestly successful at predicting functional shRNA constructs [90, 169]. Based on a set of 190 shRNAs to 19 targets, Li and colleagues [90] found several nucleotide

**Figure 3** Expression of shRNA using constitutive or inducible promoters. Example designs of shRNA constructs. (A) Three basic one-promoter systems using RNA polymerase II and III promoters. In the third construct, expression as part of the miR30 microRNA is accomplished by replacing the miR30 stem sequence with the shRNA. The shRNA sequence shown is for illustration purposes only; it has not been designed to knock down any particular gene. (B) Cre-mediated regulation of shRNA with pSico constructs in tissues expressing Cre recombinase. The loxP sites flank a stuffer sequence (in this case, GFP). Cre-mediated excision creates a functional U6 promoter allowing shRNA expression. Alternatively, the loxP sites may flank U6-shRNA instead of CMV-GFP for "off" regulation by Cre excision (pSicoR, not shown). (C) "Repression" model: regulation of shRNA expression by tet-inducible systems. A fusion protein of KRAB and tetR binding to tetO causes inhibition of shRNA and GFP expression. The presence of doxycycline releases KRAB-tetR (by binding to tetR) and permits transgene expression. "Activation" model: the presence of doxycycline induces rtTA binding and allows for transgene expression. See text for more detail. mpA, minimal polyadenylation signal; pA, polyadenylation signal; GFP, green fluorescent protein; IRES, internal ribosome entry site; tetR, tetracycline repressor; tetO, tet operator; TRE, tetracycline response element; rtTA, tetracycline transactivator; KRAB, Kruppel-associated box domain.

preferences in potent, functional shRNAs that may aid in hairpin design (Table 2). Additionally, there are other design parameters specific for shRNA constructs. The most widely used stem lengths are 19–21 bp to avoid potential toxic effects. In fact, it has been proposed that a single nucleotide mismatch created in the middle of the sense strand may further curb toxicity by limiting dsRNA length to ≤ 11 bp [29]. Loop lengths are 4–10 nt, although there is evidence that a 9-nt loop may yield a more potent shRNA in the context of a 19-bp stem [90]. If using a RNA polymerase III promoter (see below), a string of 4≤ thymidines should be avoided to prevent premature transcription termination.

Once shRNA hairpins are designed, it is necessary to test efficacy in vitro before proceeding to in vivo work. At least four or five candidates should be tested target-

**TABLE 2 Design Considerations for Effective shRNAs**

ing different sites of the mRNA transcript. The methods to accomplish this are identical to those described to test siRNA potency.

### 5.2 Promoter Selection

The in vitro expression of shRNA from both RNA polymerase II [35, 190] and III [16, 121, 164] promoters has been reported. The RNA polymerase III U6 and H1 are the most commonly used promoters as they possess a number of advantages. First, these ubiquitous promoters allow for a high level of expression in most cell types. Second, U6 and H1 contain well-defined transcriptional start sites and stop signals (four to six consecutive thymidines) that yield a 2-nt, 3′ overhang. Lastly, both have been used successfully to express shRNA in vivo [21, 36, 65, 117, 177, 184]. One study directly compared U6 and H1 silencing efficiency in mouse brain and found that U6 was superior [98]. The disadvantage of using RNA polymerase III promoters is the lack of tissue-specific expression. However, this problem may be circumvented by appropriate vector selection or use of a *Cre*-mediated activation or deactivation strategy [154, 171, 175]. For example, the pSico vector system is designed such that loxP sites flank a green fluorescent protein (GFP) expression cassette, located 5′ to the shRNA sequence (Fig. 3) [175]. When used in transgenic mice expressing *Cre* recombinase driven by a tissue-specific promoter, shRNA expression is exclusive to this tissue [175].

Transcripts generated by RNA polymerase II are structurally more complex than those generated by RNA polymerase III, as they include 5′ end caps and 3′ polyadenylated tails, which could potentially interfere with processing of the shRNA. However, discovering that cellular microRNA are transcribed from RNA polymerase II promoters, opened the possibility to use this type of promoter for expression of shRNA. The cytomegalovirus (CMV) promoter has been used to express shRNA directly, using a minimal polyA sequence [181], and in the context of the miR30 transcript [163, 189, 191]. Replacing CMV with a tissue-specific promoter is a tangible design. Experimental design may require temporal silencing of a gene to study functionality. To this end, an inducible construct to express shRNA can be used. Most inducible shRNA vectors used in vivo are responsive to ecdysone [135] or are based on the *Escherichia coli* tetracycline resistance operon. In this case, expression of shRNA is controlled by treatment with a tetracycline derivative (usually doxycycline) in several possible ways, depending on vector design. In the "repression" model, the placement of a tetracycline operator (tetO) in the shRNA promoter allows for the binding of a tetracycline repressor protein (tetR) and, consequently, transcription is inhibited in the absence of doxycycline [24, 31, 101, 102, 174]. However, this design has been shown to exhibit leaky expression in a number of studies [60, 93, 102]. Inserting a second tetO sequence [60] or using a codon-optimized tetR gene [150] appears to abrogate the leaky expression. A further adjustment to the "repression" model involves fusing the Kruppel-associated box (KRAB) domain to tetR [165, 178] (Fig. 3). The KRAB domain induces the local formation of heterochromatin, effectively blocking gene transcription with the added benefit of tighter expression compared to tetR-only vectors. Since this blockage affects both RNA polymerase II and III promoters, an internal marker, such as GFP, can be included in the vector for monitoring shRNA expression [178]. More importantly, any protein (i.e., a mutated variant) could be expressed concomitant with the shRNA to examine more complex conditions [178].

An alternative tetracycline "activation" model can be used where instead of tetR, a reverse tetracycline transactivator (rtTA) is expressed. Binding of rtTA to a tet-responsive promoter element (TRE) induces shRNA expression in the presence of doxycycline [37, 132, 163]. However, activation model constructs may suffer from greater leakiness when compared to repression model constructs [132].

### 5.3 Vector Selection

Delivery of the shRNA-expressing construct to the cell type or tissue of interest requires careful consideration. While in vitro work can utilize chemical transfection reagents and plasmid DNA, researchers have turned to viral vectors as a convenient delivery method for use in vivo. The most popular and well-characterized viral vectors are discussed here (Table 3).

**TABLE 3 Vector Systems for shRNA Expression at a Glance**

| Vector | Major Advantages | Major Disadvantages | In vivo Application Reference |
|---|---|---|---|
| E1-deleted adenovirus | Rapid production | High immunogenicity in vivo | 114, 143, 168, 181 |
| Helper-dependent adenovirus (HDAd) | Low toxicity *in* vivo<br>High cloning capacity | Difficult production methods | 177 |
| Adeno-associated virus (AAV) | Low toxicity in vivo<br>Wide range of serotypes for tissue specificity and repeated treatments | Lag in shRNA expression<br>Toxicity has been observed when expressing shRNA in liver | 21, 53, 125, 176 |
| Lentivirus | Integration of virus genome into the cell genome<br>Cell division is not necessary for transduction | Integration-induced mutagenesis | 11, 27, 33, 49, 77, 142 |

Adeno-associated viruses (AAV) are small, single-stranded DNA viruses highly used in the field of gene therapy [19]. While the best characterized serotype, AAV2, transduces a wide range of cell types, several other serotypes were shown to transduce certain specific tissues with greater efficiency. For detailed information on AAV biology and tissue specificity, we recommend reading recent reviews [52, 180]. As is the case with most viral vectors, true tissue-specific expression requires the use of a construct containing a tissue-specific promoter. Site-specific injection of the optimal AAV serotype is also an option and works well in the context of a self-contained organ, such as the eye or brain, limiting vector distribution. Disadvantages of this vector in the context of shRNA expression include a significant delay in transgene expression on the order of weeks—depending on serotype [180]. Also, AAV is known to form high-molecular-weight DNA concatemers [20]. This property could make it difficult to determine optimal vector doses and result in toxicity as extremely high amounts of shRNA are expressed. Nevertheless, AAV shRNA-expressing vectors have been used successfully in a number of in vivo studies [21, 53, 125, 176].

Adenovirus vectors have the capability of transducing a wide variety of cell types and are easily produced [123]. Earlier first-generation versions of adenovirus vectors were engineered with deletions in E1 and E3 genes. However, low levels of remnant viral gene expression lead to cytotoxicity and a cellular immune response, which precluded the use of these vectors for long-term studies in vivo [32, 108, 116]. A vast improvement in toxicity was seen when all viral genes were deleted, leaving only the inverted terminal repeats (ITRs) and packaging sequence. These vectors became known as helper-dependent (HDAd), high-capacity, or "gutless" adenovirus and were shown in numerous in vivo studies to yield long-term transgene expression [109, 111, 118, 137, 145]. Although highly efficient transduction of the liver is achieved with intravenous injection, localized applications of HDAd in the brain [170, 183, 194], muscle [26, 41], and lung [172] have also seen reasonable success. A few studies have shown it is possible to obtain a significant level of gene silencing using first-generation vectors [114, 143, 168, 181]. HDAd remains a better choice for expressing shRNA constructs in vivo [65, 177], and we have successfully used this system in liver [177]. We do not recommend the use of first-generation adenovirus vectors to express shRNA in vivo. In addition to the toxicity and lack of persistence in tissues associated with this vector system, first-generation vectors express VA1 noncoding RNA known to interfere with the RNAi processing pathway [95].

Lentiviruses, a member of the retrovirus family, have become useful tools for gene delivery. Transduction of both dividing and nondividing cells are possible [74, 113]—particularly when pseudotyped with the vesicular stomatitis virus G (VSV-G) envelope [3]. Other pseudotypes with improved tissue specificity are also available but are not as well characterized (reviewed in [28]). Viral-mediated cellular toxicity is largely not an issue as lentivirus vectors do not express viral proteins. Lentiviruses have been used in conjunction with shRNA for in vivo [23, 27, 49, 98] and ex vivo [11, 117] experiments. In contrast to AAV and adenovirus vectors, lentivirus vectors efficiently integrate into the host cell genome and do not require cell division for integration. This characteristic not only eliminates vector dilution effects by cell division but allows for an alternative to traditional knockouts. Several examples exist of success using the lentivirus/shRNA as a system to generate transgenic mice with silenced genes [33, 77, 142, 171, 182]. However, potential difficulties with epigenetic vector silencing and genetic mosaicism may impact the usefulness of this strategy [124].

## 6 APPLICATIONS

### 6.1 Treatment of Human Diseases

The field of RNAi therapeutics is advancing at a very rapid pace, and there are currently several clinical trials

at either phase I or phase II/III (for detailed information visit www.clinicaltrial.gov). Other treatments are at a preclinical stage, and proof of concept has been provided from studies in animal models.

***Infectious Diseases*** In therapies aimed at treating viral diseases, the siRNA is directed against a viral RNA transcript, replication intermediate, or a cellular component necessary for the virus to replicate. Clinical trials have started for the treatment of respiratory syncytial virus (RSV). Alnylam Pharmaceuticals has recently finished a phase II study in approximately 88 volunteers with experimental RSV infection (i.e., patients were infected with a clinical strain of the the virus). ALN-RSV01, an siRNA to target a component of the nucleocapsid of RSV, was administered intranasally once a day for 5 days. Antiviral activity in the absence of toxicity was observed (press release). A phase II study in patients with natural infection with RSV is planned for the near future. Another clinical trial to be started in the near future involves a combinatorial therapy using lentivirus vectors to treat HIV infection [91, 141]. In this ex vivo approach, hematopoietic progenitor cells are transduced with a lentivirus expressing an shRNA directed against tat/rev (essential proteins for virus replication), a ribozyme against the cellular co-receptor CCR5, and a nucleolar localizing transactivation responsive (TAR) RNA decoy [91].

***Central Nervous System (CNS) Diseases*** Using viral vectors, several studies in mice have shown considerable success at silencing the genes involved in gain-of-function conditions such as Huntington's disease and familial amyotrophic lateral sclerosis (ALS) [58, 107, 133, 136]. Huntingon's disease is a neurodegenerative disorder caused by the presence of polyglutamine repeat expansions in the huntingtin protein, resulting in a gain of function. Harper and colleagues have used AAV1 to knock down a mutant form of huntingtin in mice, which led to improved behavioral and neuropathological abnormalities [58]. Similarly, lentiviral vector-mediated shRNA expression in animal models of ALS, a disease caused by mutations in the superoxide dismutase gene, has also proved the concept that RNAi may represent a valuable treatment for this gain-of-function disease [133, 136]. Although no clinical trials have started yet, Alnylam Pharmaceuticals has conducted preclinical studies in mice showing that cholesterol-conjugated siRNA to target huntingtin by intrastriatum infusion is a valid approach to attenuate the neuronal and behavioral abnormalities characteristic of the disease [39].

Delivery of siRNA to the CNS, however, remains a challenge. Several groups have shown it is possible to silence a gene through direct injection of siRNA in the brain. There have been efforts to administer the siRNA by stereotaxic surgery, but usually this route results in transfection being restricted to the area close to the injection site. Nevertheless, this route is unacceptably invasive for the treatment of human conditions. Intrathecal siRNA infusion has been used successfully to reduce levels of the pain-related cation channel $P2X_3$, reducing the response to pain [40]. Intravenous administration represents a more viable delivery route, but poses the challenge of crossing the blood–brain barrier. A possibility to overcome this limitation is to take advantage of the fact that neurotropic viruses can cross the blood–brain barrier. Peptides from their envelopes can be used for targeted siRNA delivery. A recent study has shown that this is a feasible approach by using siRNA complexed to a cell-penetrating peptide and a rabies virus glycoprotein (RVG) peptide. The RVG peptide confers neuron specificity by binding to acetylcholine receptors, while the cell-penetrating peptide provides a way to bind the siRNA through charge interaction. The siRNA was found widely distributed in all areas of the brain and was not detectable in liver or spleen. Approximately 50% gene silencing was observed [79].

***Age-Related Macular Degeneration*** Age-related macular degeneration (AMD) is a disease for which gene therapy approaches had already been pursued, and some of the molecular pathways involved were relatively well known. AMD is characterized by damage to the central area of the retina (macula), resulting in loss of vision. Abnormal growth of vessels causes the less common form of the condition, called wet AMD. Opko Health, Inc., developed Cand5 (Bevasiranib), a siRNA to target vascular endothelial growth factor (VEGF), a molecule involved in neovascularization of the retina. The reagent is administered by direct injection into the vitreous. Cand5 displayed good safety profiles and signs of biological activity in phase II trials in patients with AMD and in patients with diabetic macular edema (Opko Health, Inc., press release). A second siRNA to target the VEGF pathway is Sirna-027 [153], which was developed by Sirna Therapeutics (currently owned by Merck & Co., Inc.). This siRNA targets VEGF receptor 1 (VEGFR1) and has been tested in phase I trials. Eight weeks after one single injection of the drug, 100% of patients showed visual acuity stabilization and a few patients had improved visual acuity (press release). A phase II trial demonstrated good efficacy (clinicaltrial.gov ID: NCT00363714). A third product, RTP-801i (Silence Therapeutics, Inc.), is currently being tested in a phase I trial (press release). Its target is the hypoxia-induced gene DNA damage-inducible transcript 4 (*DDIT4*) [13].

***Cardiovascular Diseases*** siRNA have the potential to become drugs for the treatment of hypercholesterolimia. In one study, administration of a cholesterol-conjugated siRNA to target apolipoprotein B (ApoB) was infused intravenously in mice. The siRNA conjugate was widely distributed and was found in liver, kidney, heart, adipose tissue, and lung [161]. In the study, it was shown that ApoB mRNA was decreased in liver and jejunum, and that ApoB protein in plasma was lower. As a consequence of the RNAi treatment, mice had a 50% decrease in chylomicron levels, a 40% reduction in the LDL concentration and a 25% decrease in HDL levels, together with a reduction in total plasma cholesterol. No effect in very low density lipoproteins (VLDL) was observed [161]. In a follow-up study, liposome-conjugated siRNA was delivered intravenously to nonhuman primates. A dose-dependent reduction in ApoB mRNA levels was observed, concurrent to a decrease in serum cholesterol and LDLs [193]. One dose was sufficient to silence ApoB for 11 days.

***Cancer*** siRNA drugs can be developed to interfere with tumor biology in multiple ways. One of the most pursued approaches has been to obstruct the angiogenesis process by targeting VEGF or its receptor, to reduce formation of blood vessels, necessary for tumor growth. In one study, an siRNA to VEGF receptor 2 (VEGF R2) complexed to an RGD peptide was delivered systemically. The RGD motif binds to integrins in endothelial cells of the vasculature, and the siRNA inhibits expression of the VEGF receptor. This approach resulted in selective tumor uptake and reduction of neovasculature and tumor size [146]. In a second study, the siRNA was directed to VEGF, and it was tested in an animal model of prostate cancer. The siRNA was conjugated to atelocollagen, which was expected to protect it against nucleases, prolonging the circulation time and increasing uptake. The siRNA was given intratumorally every 10 days at the initial stages of tumor development. At day 50, tumors were significantly smaller and had much lower levels of vessel density than those treated with a control siRNA [166]. In a more recent study, Kim and colleagues showed that anti-VEGF siRNA conjugated to cholesteryl oligo-D-arginine reduced tumor and neovascularization in a model of colon adenocarcinoma [75]. The use of siRNA as a tool to prevent the onset of metastasis has been addressed in a study to knock down the Ewing sarcoma breakpoint region 1-Friend leukemia integration 1 transcription factor (EWS-FLI1) fusion gene product in a mouse model of metastatic Ewing's sarcoma [64].

Another approach has been to target genes that are overexpressed in tumor cells. One example includes generating an aptamer-siRNA chimera to target prostate cancer cells. The aptamer portion bound the prostate-specific membrane antigen (PSMA), while the siRNA was designed to target the genes polo-like kinase 1 (PLK1) or the proto-oncogene B-cell leukemia/lymphoma 2 (BCL2), which are overexpressed in tumors [105]. In a xenograft model of prostate cancer, the chimeras prevented tumor growth in PSMA-positive cells but not in PSMA-negative cells [105]. Glioblastoma multiforme is one of the most aggressive brain tumors, with a poor prognosis. The growth factor pleiotrophin is overexpressed in these tumors, which can be used as a siRNA drug target. In a mouse model of brain cancer, administration of a polyethyleneimine-complexed siRNA against pleiotrophin reduced the tumor size by 50% [54]. Finally, treatment with chitosan-coated siRNA to target a low-molecular-weight GTP/GDP-binding GTPase, Ras homologous A (RhoA), reduced the tumor size by 90% in a model of breast cancer [131].

### 6.2 Gene Function Studies and Drug Target Identification

RNAi has become the preferred tool for identification of new targets and to study gene function. Traditional technologies to validate the role of genes in disease involve the development of animal models with null alleles for the target gene. In some instances, absence of a gene is incompatible with normal development, leading to death in utero. In addition, for particular studies it may be necessary to knock down gene function in the adult animal (instead of at the stem cell level), thereby providing a model similar to the human condition. One example of such an application would be to study the effect of reducing a gene product that is known to be upregulated in animal models of diet-induced obesity.

The limitations of using RNAi for gene function studies and target validation are similar to those described for the use of this technology as a therapeutic treatment, that is, presence of unspecific and off-target effects that may mask the real impact of knock-down on the gene of interest. Induction of unspecific effects such as the interferon response, is siRNA concentration dependent [129], and cell type dependent [139]. Therefore, data generated in one tissue may not apply to another, and pilot studies should be conducted in the tissue of interest. Unintended targeting can be mediated by any of the dsRNA strands that are generated from shRNA processing. Thus, carrying out experiments with more than one siRNA/shRNA sequence is desirable, to confirm that the impact of silencing the gene of interest in the cell/animal is due to on-target rather than off-target effects.

Numerous gene function studies have been conducted using RNAi. For example, to investigate the role of the gene defect in acute myeloid leukemia (AML), Heidenreich and colleagues used an RNAi-mediated approach [59]. Translocation between chromosomes 8 and 21 results in the fusion gene *AML1/MTG8*. By designing an siRNA to specifically target the fusion protein (leaving the wild-type protein unaffected), the authors were able to show that leukemic cells transfected with siRNA to the fusion protein were susceptible to the action of tumor growth factor β1, inducing cell differentiation, and providing evidence for a role for *AML1/MTG8* in preventing differentiation and promoting cell division [59].

RNAi is also being used in target validation studies. Brusselmans and colleagues explored the possibility of using acetyl-CoA carboxylase α (ACC-α) as the target for prostate cancer treatment, taking advantage of the fact that de novo lipogenesis is upregulated in many cancer cell types, while noncancerous cells have low levels of the enzymes involved in this process [17]. Treatment of LNCaP cancer cells with a siRNA against ACC-α resulted in reduced phospholipid and triglyceride synthesis levels, followed by subsequent induction of caspase-mediated apoptosis. Although the siRNA molecule could also induce gene silencing of the target genes in normal fibroblasts, apoptosis was not observed in these cells [17], suggesting that ACC-α is a good target for treatment of prostate cancer. Thus, RNAi can be used to conduct studies testing the role of genes in disease and simultaneously provide the proof of concept for target validation.

## ACKNOWLEDGMENTS

Our research is funded by grants from the NIDDK (DK069432-01 and DK078595), American Diabetes Association (1-08-RA-135), INGEN (Indiana Genomics Initiative of Indiana University supported in part by Lilly Endowment Inc.), and by the American Heart Association (fellowship to SRW).

# CRYSTALLOGRAPHY

Carl H. Schwalbe
*School of Life & Health Sciences, Aston University, Birmingham, United Kingdom*

## 1 INTRODUCTION

In the hierarchy of methods for structure determination, crystallography is the monarch. A technically correct crystal structure determination on high-quality material approaches as close to infallibility as any human effort can do. This degree of certainty comes at a cost: It requires a properly crystalline sample and uses sophisticated expensive apparatus. This chapter first aims to give a general overview of what crystallography can contribute to drug discovery. A discussion of practical matters follows, covering required features of the crystalline sample, the radiation source, and the detector. Next, the essentials of the underlying theory are introduced so that the rationale for the steps in a crystal structure determination can be understood. Although crystallography is underpinned by mathematics, the treatment here will be as intuitive as possible with limited recourse to mathematics. The narrative then returns to specific examples of the use (and nonuse) of crystallography in drug discovery.

### 1.1 Discovering an Unknown Structure

For many years crystallography has provided the definitive proof of structure for a novel small molecule. Only one sample crystal is usually needed, and this specimen crystal remains available for further studies. Such economy of material is of particular value if, for instance, a very small quantity of a natural product has been isolated. If just the connectivity of the molecule is required, spectroscopy [especially nuclear magnetic resonance (NMR)] is generally sufficient, but crystallography removes any doubt and additionally provides geometric data like bond distances and angles. Crystallographic location of hydrogen atoms is less certain since X rays respond weakly to hydrogen atoms. Nevertheless, hydrogen atom positions can frequently be inferred from the molecular geometry and subsequently confirmed in a map. For instance, a carboxyl group in the free acid form has a short C=O bond and a longer C–OH bond, while a carboxylate ion has two similar C–O distances. If precise details of hydrogen atom geometry are necessary to understand the activity of a particular drug, neutron diffraction provides this information.

Crystallography is of key importance for macromolecules. Revolutionary technical advances have improved the productivity of macromolecular crystallography from a few structures per year in the 1960s to many thousands now. This is fortunate since the Human Genome Project has provided a wealth of new macromolecules whose structure and function need to be investigated. Once again, NMR provides a complementary technique. However, it has the great disadvantage of requiring inference, which could be wrong, although it does have the advantage of sampling all populated conformations in solution. Crystal growing necessarily freezes out most of the motion and selects one or a few conformations that pack together well.

### 1.2 Structure-Based Drug Design

In the ideal case the detailed three-dimensional structure is known for a target macromolecule whose function needs to be inhibited or enhanced by therapeutic intervention. Likewise the structures are known for some lead compounds, chosen by molecular modeling or high-throughput screening. Additional crystal structures are determined for the drug–target complexes, and the important binding contacts are identified, along with any regions of poor steric fit. Using such information in an iterative process, successive generations of drugs are made to have stronger binding and greater selectivity.

If the structure or even the identity of the target macromolecule is not known, crystallography can still be useful. From the structures of a series of active drugs and closely related inactive molecules, a *pharmacophore model* can be developed, comprising chemical groups (e.g., hydrogen bond donors, hydrogen bond acceptors, or aromatic rings) and the spatial relationships between them. Such a model is especially useful to screen out hopeless candidate molecules before synthetic effort is wasted on them.

### 1.3 Relating Crystal Structure to Properties

There are obvious correlations between molecular geometry and chemical reactivity; for instance, a longer bond between a defined pair of elements is a weaker bond, likely to be more reactive. Crystal structures also help to address formulation issues for solid dosage forms. Two conflicting objectives have to be met. A long shelf life correlates with a stable solid; but good bioavailability requires adequate aqueous solubility, which is more easily achieved with an unstable solid. The same drug may exist in multiple crystal forms (*polymorphs*) having identical chemical composition but different structure, leading to differences in stability, melting point, solubility, and handling properties. Aqueous solubility in a series of salts of a drug does not always correlate with hydrophilicity of the counterion, showing the importance of structure. The pharmaceutical industry has invested heavily in robotic technology to screen new drugs for polymorphs and find the most suitable counterion in a salt. If neither the neutral drug nor a simple salt has the desired properties, the investigation can be extended to co-crystals with other drugs.

### 1.4 Crystallography without a Crystal: Data Mining

Pharmaceutical use of crystallography has been greatly enhanced by the compilation of two databases: the Cambridge Structural Database (CSD) with hundreds of thousands of small molecules (www.ccdc.cam.ac.uk) and the Protein Data Bank (PDB) with tens of thousands of macromolecules (www.rcsb.org/pdb/). One crystal structure of a flexible drug molecule may show a conformation that is dictated by crystal packing and unrepresentative of the preferred conformation in solution or at a receptor. However, if that same conformation occurs in crystal structures of related molecules in the CSD, it is likely to be stable. If the structure of a target macromolecule is available in the PDB, it provides a sound basis for drug design. Frequently, the structure is only available for a related protein or the same one from a different organism. If so, *homology modeling* can be attempted. The backbone is retained, the amino acid side chains are adjusted to match the sequence of the new target, and strains are relieved by optimization with molecular mechanics calculations.

### 1.5 Crystal Structure Prediction

If crystal structures could be reliably predicted, the effort of determining them experimentally could be avoided. It is fairly straightforward to predict the crystal structure of a simple small molecule. Unfortunately, the correct structure is usually accompanied by several dozen incorrectly predicted structures that seem just as good according to the common-sense criteria of low energy and high packing density. A major research effort is underway to develop prediction methods that discriminate better between correct and incorrect structures. Progress has been assessed in a series of blind tests. With the authors' consent publication of a few novel crystal structures has been held back for a few months. Diagrams of the molecular connectivity have been sent to participating research groups, who have been asked to apply their prediction software during this period and to return their best three predicted crystal structures for each molecule. The results of the third blind test (2004) showed that good progress has been made in predicting crystal structures built from a single copy of a small rigid molecule, but flexible molecules still cause insuperable difficulty [1].

## 2 PRACTICAL MATTERS

### 2.1 The Sample Crystal

The definition of a crystal is one source of misunderstanding between crystallographers and organic chemists. Organic chemists tend to judge the macroscopic external appearance, but to be suitable for crystallographic use the sample crystal has to possess an internal structure that is a regular repeating array of atoms, mol-

**TABLE 1 Summary of Techniques Used for Crystal Growing**

| Method | Requirements | Advantages | Disadvantages | Uses |
|---|---|---|---|---|
| Slow evaporation | Moderately soluble sample | Easy, gentle | Long exposure to air; drying out leaves a crust | Small molecules |
| Slow cooling | Large variation of solubility with temperature | Easy | Cooling must be controlled; initial heating risks decomposition | Small molecules |
| Vapor diffusion | Sample dissolves in one solvent; vapor of poorer solvent can diffuse | System can be protected by sealing and cooling | Solvent pair must have correct solvent power and volatility | Macromolecules, small molecules |
| Liquid diffusion | Sample in good solvent; less dense poor solvent layered on top | System can be protected by sealing and cooling | Solvent pair must have correct solvent power and density | Small molecules, macromolecules |
| Sublimation | Volatile sample evaporates, then crystallizes on cooler surface | No unpredictable interactions with solvents | Risk of decomposition | Small molecules |

ecules, or ions. It must have smooth edges and no reentrant angles, that is, "bays" flanked by "headlands," which are indicative of more than one crystal stuck together. A polarizing microscope is a cheap and extremely useful part of any crystallography laboratory. All but the most highly symmetrical crystals rotate the plane of polarized light. If such a crystal is viewed between crossed polarizers on a slowly rotating microscope stage, both the crystal and its surroundings will appear black until the appropriate angle is reached where the crystal rotates the light so that it can pass the second polarizer. At that point the crystal will flash into brightness and soon after subside back into darkness. If the changes are sharp and uniform, the crystal is expected to be single and of high quality. Uniform but more diffuse changes suggest lower quality, while illumination of only part of the crystal shows that it is not single.

***Crystal Growing Techniques*** Crystal structure determination relies on the ability of a crystal, irradiated with a parallel beam of X rays or neutrons, to produce diffracted beams that can be measured. Specimen crystals must be of high quality and about 0.4 mm across to match the typical X-ray beam size, or >1 mm across if used for a neutron diffraction experiment. The most appropriate method for growing them depends greatly on the properties of the particular material, but some general principles apply. The initial sample should be reasonably pure. While recrystallization is a standard technique for purifying chemicals since the growing crystals exclude impurities, such impurities are likely to impede growth on certain faces leading to small size and distorted crystal morphology. Glassware should be well but not obsessively cleaned. Dust particles often provide nucleation sites for crystal growth: Too many and the crystals will be too small; none at all and crystals may not form. Patience is a great virtue: Provided the material is stable, slow growth will yield the largest and most perfect crystals.

The most used methods for growing "X-ray quality" crystals are enumerated in Table 1.

Public-spirited individuals have placed helpful guidance notes on the Web. Two that can be recommended are "Growing Crystals That Will Make Your Crystallographer Happy" by Paul D. Boyle [2] and paired contributions both entitled "Crystal Growing Tips" by Maarten Dinger and Jerzy Klosin [3]. In turn these notes cite useful books. Techniques for improving protein crystals used in diffraction experiments have been comprehensively surveyed [4].

### *Crystal Pathology*

*Twinning* A common problem with crystal growing is that crystals may grow together or stick together. If a large high-quality specimen crystal has a small randomly oriented "flea" stuck to it, it may be wiser to tolerate the situation than to risk cutting the crystals apart. The small flea will give weak diffracted X-ray beams, and most of them will not coincide with diffracted beams from the main crystal. Major difficulties arise if two or possibly more adhering crystals are nearly equal in size and their orientations are related by rotation or reflection. Such crystals are *twinned*. Twinning usually arises when crystal axes are exactly or approximately at right angles to each other. If the axes are exactly perpendicular, 180° rotation about one axis will leave the other two coincident but pointing in opposite directions. In this case, *merohedral twinning*, measuring

the diffracted beams is not difficult since the beams from the two crystals coincide, but interpreting them is much more difficult. If the axes are nearly but not quite perpendicular, the diffracted beams will no longer coincide but may overlap. This case, *nonmerohedral twinning*, causes problems in both measurement and interpretation. Modern hardware and software can cope with twinned specimen crystals, but it is far better to avoid them if possible.

*Thermal Motion and Disorder* Even though the *average* positions of molecules in a perfect crystal are fixed in an orderly array, the molecules and their component parts are vibrating. The atoms are properly represented not as points but as the ellipsoids they trace out, which are displayed in the familiar "ORTEP plots" [5] in crystal structure papers. Besides degrading the precision with which the molecular geometry can be determined, such vibrations can introduce a small systematic error into bond distances. Because it is hard to stretch a bond but easy to bend one, thermal vibration tends to make a bonded atom trace out an arc around its bonded partner atom. Since the centroid of the arc lies within the radius of the arc, the bond distance appears slightly too small. To reduce such effects and also to promote crystal stability, data collection is increasingly being carried out at low temperature. Low temperature is particularly important for macromolecular crystals, which tend to be very sensitive to radiation damage. While simply freezing such a crystal is likely to cause even more damage, initial treatment with a cryoprotectant such as 25–35% glycerol followed by flash-freezing stabilizes the crystal and provides improved data.

A side group on a molecule, such as a pendant ethyl or isopropyl group, may not be tightly surrounded by neighbor atoms within the crystal on all sides. Such a group in one molecule may flip back and forth between alternative conformations (*dynamic disorder*), or molecules in different domains within the crystal may adopt one or the other alternative conformation (*static disorder*). The disordered atoms have to be treated as occupying more than one site, with each one having fractional occupancy.

*Crystal Size versus Beam Size* A crystal structure determination relies on the measurement of X rays or neutrons diffracted by the sample crystal. Because a very small crystal can only provide weak diffracted beams with a poor signal/noise ratio, there is an understandable desire to work with large specimen crystals. However, the maximum allowable size of crystal is limited by several sources of serious error. First of all, the crystal must fit within the uniformly intense portion of the beam irradiating it. If part of the crystal projects beyond this region, then as the crystal is turned during the measuring process, the mass of material interacting with the beam is likely to vary, introducing errors.

*Absorption* Irradiated crystals not only diffract the incoming beam, they tend to absorb some of it too. "Heavy" atoms, actually those with a high atomic number, are effective at absorbing X rays as well as diffracting them. From data in the International Tables for X-ray Crystallography, also stored in popular software such as the SHELX suite [6, 7], it is possible to calculate an absorption factor $\mu$. As a rule of thumb, if no dimension of the crystal exceeds $1/4\mu$, absorption will not be much of a problem. For a crystal composed only of C, H, N, and O atoms, this will allow the 0.4 mm size mentioned earlier for X rays. If heavy atoms are present, the optimum size may be much smaller. Larger crystals will require an absorption correction, supported by measurements if at all possible.

*Extinction* This phenomenon requires mathematical analysis, but an intuitive explanation is that when a large perfect crystal is efficiently producing a diffracted beam, the incident beam is weakened before it reaches deeper layers of the crystal. Thus, these deeper layers produce less than their expected contribution to the diffracted beam. The discrepancy is most pronounced when diffraction is most efficient. Good correction routines are available in many software packages.

***Powder Samples and Their Usefulness*** As will be shown subsequently in the brief section devoted to theory, the crystal must be set at exactly the appropriate angle to the incoming beam in order to generate a particular diffracted beam, and this operation must be repeated many times to obtain a full set of measurements. This requirement adds to the complexity of the apparatus but makes it clear which diffracted beam is currently being measured. If the sample is a powder instead of a single crystal, it will contain a huge number of tiny crystallites. For any possible diffracted beam some of these crystallites will be at the appropriate angle to the incoming beam, and thus a large number of diffracted beams can be measured all at once. The measurement process is both cheaper and quicker. However, the attribution of measured intensity to particular diffracted beams is lost, and interpretation requires pattern matching, much like the fingerprint region in an infrared spectrum. If reliable standard powder patterns exist for a particular drug, this technique can be valuable for quality control. The Powder Diffraction File, maintained by the International Centre for Diffraction Data (www.icdd.com), provides a database of such measure-

ments. In particular, unlike chemical analysis, powder diffraction can make clear which polymorph is present in a sample.

Recently, methods have been developed that make it possible to carry out a full three-dimensional structure determination from a powder sample. These are not routine procedures and may depend on good fortune in initial trial-and-error attempts to find a starting model, but they are of great value when all attempts to produce larger crystals end in failure.

### 2.2 Radiation Source

***Sealed Tube*** The humble X-ray tube is a technological marvel! As shown in Figure 1, a focused beam of electrons is accelerated by a high voltage, typically around 50 kV, and smashes into a metal anode, usually made of copper or molybdenum. In the sort of fine-focus tube generally used for single crystals of drugs, the same power as a domestic electric heater (1.5 or 2 kW) falls upon a spot $0.4 \times 8$ mm. A rapid circulation of cooling water is essential to carry away the heat produced; and if this circulation fails, the tube will be a write-off. The water circuit is protected by an internal filter in the tube and possibly by an external filter as well. Cleaning these filters is a necessary chore most laboratory staff try to avoid, but restricted water flow may lead to overheating and distortion of the anode that will impair the beam quality. Delivering a focused electron beam requires a vacuum in the tube. Molecules from the air slowly leak in but are driven to the walls by collisions with the electron beam. A stored X-ray tube should be operated every few months so that this self-cleaning mechanism can work.

Many of the electrons impacting the anode are stopped in their tracks. An accelerated (in this case decelerated) charge emits radiation, and for the energies described here the radiation comes in the form of X rays. This "white" radiation has a continuous range of wavelengths and energies and is useless for most purposes. Some of the bombarding electrons knock out inner shell electrons from the metal atoms in the anode. Outer shell electrons fall in to fill the vacancy, emitting X rays of defined energy and wavelength that are characteristic of the target metal. This wavelength is approximately 1.54 Å for copper and 0.71 Å for molybdenum (1 Å = $10^{-10}$ m). The critical excitation voltage that is just sufficient to enable a bombarding electron to knock out an inner electron is 9 kV for copper and 20 kV for molybdenum. Greater efficiency is achieved at higher voltage; hence 40–55 kV is typically used.

The long narrow focal spot is viewed almost edge-on at a take-off angle of around 6° by a collimator typically 0.4 to just over 1 mm in diameter, directing a parallel beam of X rays at the sample. Unwanted wavelengths of radiation are removed by a monochromator containing a crystal, usually graphite, which reflects them in directions where they miss the collimator and get absorbed by the metal housing. The desired radiation is Kα, meaning that an electron has been ejected from the innermost K shell of the target and replaced from the adjacent L shell. Kβ is produced when the replacement electron comes from one shell farther out, the M shell. Along with all the white radiation, it needs to be removed by the monochromator.

**Figure 1** Schematic diagram of an X-ray tube used for crystallography [8]. (Reprinted with permission from IUCr.)

***Rotating Anode*** Higher power can be achieved by replacing the static anode with a rotating disk so that the heat production is spread out along the circumference. The enhanced beam intensity is particularly useful in protein crystallography, where a large quantity of data must be collected before the often unstable crystal degrades. However, the provision of cooling and vacuum seals for a rotating object is much more difficult. An active pumping system is required to maintain the vacuum, and acquisition and maintenance costs are higher.

***Focusing Optics*** The operation of an X-ray tube is inherently wasteful, with much of the energy input going into the production of heat or X rays of the wrong

wavelength. Furthermore, even those X rays with the correct wavelength may be emitted in the wrong direction. Devices to redirect these wayward X rays toward the sample can provide a useful enhancement of beam intensity.

***Synchrotron*** Once again the principle that an accelerated charge emits radiation is applicable. The electrons constrained in a circular path in a synchrotron undergo never-ending centripetal acceleration and therefore emit radiation. In the form of X rays this radiation posed a safety hazard for the early accelerator physicists. More recently, publicly funded synchrotrons have been purposely built in most major countries to serve X-ray scientists. Insertion devices (wigglers or undulators) bend the beam to generate X rays of a desired wavelength at a predetermined location. Access to such beamlines is now available to many scientists by competitive application, and some pharmaceutical companies have purchased block bookings of beam time for their researchers.

The main advantage of a synchrotron source is that the limitation on intensity posed by the heat tolerance of a target is removed. The much more intense beam enables data to be collected much more rapidly. Another great advantage is that the X-ray wavelength is not fixed by the choice of target metal but instead can be tuned. This permits the optimal use of anomalous scattering, which will be described later.

***Neutron Diffraction*** All the radiation sources discussed so far produce X rays. The first step in the process of X-ray diffraction, to be explained in more detail later, is where the X rays are absorbed and then reemitted. In ordinary matter this process is carried out most efficiently by the electrons, and the final product of the analysis is a map of electron density in the molecule. For nearly all elements the electron density around an atom is virtually spherical and the location of that atom is easily inferred. However, the only electron possessed by a covalently bonded hydrogen atom is shared with another atom. The apparent position of such a hydrogen atom deduced from the electron density is too close, by roughly 0.1 Å, to the other atom, and the location is poorly defined. Unfortunately, in many pharmaceutical molecules this location is exactly the information most needed since hydrogen bonding strongly influences their structure and mechanism and it may be important to know whether a hydrogen atom has been transferred from an acid to a base. Neutrons, on the other hand, interact with the atomic nuclei and reveal their location accurately, even for hydrogen atoms.

The only practical neutron sources are at large centrally operated facilities, either nuclear reactors or spallation sources. Fission reactors operate by means of a neutron reaction (SNS) in which a fissionable nucleus absorbs a neutron, becomes unstable, and splits into smaller fragments including a number of neutrons that can attack other fissionable nuclei. Some of these surplus neutrons can be led away from the reactor core. Although we usually think of neutrons as particles, they also have wave properties that can be exploited for diffraction. After some contact with materials at room temperature their energy is reduced to the point that their wavelength is suitable for crystallography. To increase the intensity of the neutron beam, fission reactors have been designed for maximum power density and hence neutron production within a small core. Such design evolution runs up against the need to maintain cooling and control of the core, along with the nervousness of residents living near the reactor.

Many recent high-intensity sources, for instance, the American facility at Oak Ridge, TN, commissioned in 2006, use the alternative spallation technique. A pulsed beam of protons from an accelerator is fired at a heavy metal target with neutron-rich nuclei. As the high-energy protons strike the nuclei, neutrons are released. Where a solid metal target is used, the risk of damage to the target has limited the proton flux that could be directed at it. The Oak Ridge SNS uses liquid mercury as the target for the first time. With constant recirculation of the mercury, a much higher intensity can be tolerated.

Because of the weakness of the available beams, the application of neutron diffraction has up to now been limited to large crystals typically greater than 1 mm on a side compared to one-tenth that length for X-ray diffraction. It is hoped that the new facilities will provide satisfactory neutron data from more normal-sized crystals.

### 2.3 Detectors

The development of detectors for X rays has followed a pendulum process, alternating between point and area detectors. When the Bragg family, father and son, made their first accurate measurements, they used an ionization spectrometer positioned to intercept one diffracted beam at a time. Subsequently, this temperamental piece of apparatus was replaced by photographic films that could record many diffracted beams at once in the form of spots. However, the intensity of each spot had to be laboriously evaluated by visual comparison with calibration spots. Robust and reliable scintillation counters were introduced in the early models of diffractometers, providing automatic readout of each diffracted beam in succession. Such one-at-a-time measurement inevitably takes days or weeks for collection of a full set of data

and often exceeds the lifetime of an irradiated protein crystal. The need for greater speed has prompted a return to area detectors in modern diffractometers.

Charge-coupled device (CCD) detectors generally have a thin phosphor screen that absorbs the energy of incident X rays and reemits it as visible light. A tapered optical fiber conveys the light to a doped semiconductor chip that provides a readout of intensity versus position by a process related to television camera technology. Multiple CCDs can be placed side by side in a matrix to enhance the area covered. Multiwire proportional counters provide a similar readout by using an alternative process of ion-pair generation in a gas-filled tube. Image plates are analogous to films. Diffracted X rays striking a phosphor excite it into a metastable state. The exposed plate is scanned with a laser operating at one wavelength, which stimulates release of the trapped energy at a different wavelength with an intensity that is proportional to the intensity of the original X-ray beam that struck that place on the plate. After scanning, the plate can be reused.

## 3 BRIEF HIGHLIGHTS OF NECESSARY THEORY

In the short sections that follow it is impossible to convey the full depth of knowledge needed by a practicing crystallographer. For this purpose the excellent courses run by national or regional crystallographic societies are recommended. Teaching materials from the British Crystallographic Association have been published in book form [9]. Around two dozen teaching pamphlets written by experts on specific topics for a carefully defined audience, usually scientists in other fields and students, are available online from the International Union of Crystallography (http://www.iucr.org/ and then select Teaching Pamphlets). The goal in this chapter is to enable understanding of the steps in a crystal structure determination and the ability to read critically a paper describing a crystal structure.

### 3.1 Introduction to Lattice and Space Group Symmetry

A crystal is composed of a regular repeating array of atoms, molecules, or ions. If these units are conceptually simplified to points, the repetition generates a three-dimensional *lattice*. Adjacent lattice points in three dimensions define a block called the *unit cell*, with lengths $a$, $b$, $c$ along the $x$, $y$, $z$ axes; and the crystal can be generated by placing a myriad of unit cells side by side with edges in register. There is no requirement that $a$, $b$, $c$ should be the same. Neither do the $x$, $y$, and $z$ axes generated by vectors from one lattice point to its neighbors have to be perpendicular. This completely general case is called the triclinic *system*. Other systems are more restricted: monoclinic has $y$ perpendicular to $x$ and $z$, orthorhombic has all three axes mutually perpendicular, tetragonal additionally has $a = b$, hexagonal also has $a = b$, but at a 120° angle, rhombohedral has all three axes equal in length but nonperpendicular, and cubic has all three axes equal and perpendicular. With lattice points just at the corners of the unit cell, the arrangement is called primitive, but it may give more efficient packing to have *centering*, that is, extra lattice points in the middle of faces or at the midpoint of the entire unit cell. There are 14 permissible combinations of crystal systems and centering types, termed the Bravais lattices.

Another way in which molecular crystals may attain improved packing is to place additional molecules into the unit cell in different orientations. These molecules may be related to the original molecule by a strict application of symmetry, or they may be independent (the so-called $Z' > 1$ situation). Racemic mixtures frequently do not separate upon crystallization. Instead, both enantiomers occupy one unit cell, related by an inversion center. Two molecules related by rotation or by mirror reflection may also occupy the unit cell. Simple rotations or reflections are rare because they often cause one part of the rotated or reflected molecule to bump into part of the original molecule. However, screw axes (rotation accompanied by translation through ½ or another fraction of a unit cell length) and glide planes (reflection accompanied by translation through ½ of a unit cell length) are common because the interleaving they produce is conducive to good packing. The combination of such symmetry elements determines the *space group*. The space group is essential information in any crystal structure publication. The most common space group is $P2_1/c$, containing all types of symmetry element just mentioned. The symbol $P$ signifies a primitive lattice, the $2_1$ refers to a screw axis, and $c$ to a glide plane. The combined operation of $2_1$ and $c$ implicitly generates an inversion center.

### 3.2 Physical Process: Diffraction

Being electromagnetic radiation, an X ray impinging upon an atom can accelerate an electron, which will then reemit the X radiation. The X rays reemitted by different electrons in the atom interfere with each other. This also applies to those from different atoms in the molecule, different molecules in the unit cell, and the contents of different unit cells. The end result is the production of an extremely complicated three-dimensional diffraction pattern that strains human comprehension. The important point to remember is that

**Figure 2** Illustration of the reference planes for calculation of Miller indices for the 111 and 221 stacks of planes [10].

diffraction of X rays is effectively caused by electrons, and the ultimate result of computer analysis of a measured diffraction pattern is a map of the electron density.

### 3.3 Understandable Analogy: Reflection from Crystal Planes. Miller Indices, Bragg's Law, and the Meaning and Importance of Resolution

The Braggs devised a much more comprehensible picture. Imagine stacks of planes cutting through the unit cell. These stacks are capable of reflecting X rays, and together they create the diffraction pattern. Since we may need to consider thousands of stacks differing in spacing and orientation, a clear system of nomenclature is essential. This requirement is satisfied by the Miller indices, which are defined next.

Arrange a stack of planes so that one plane goes through the origin of the unit cell. The next plane in the stack is the reference plane. This plane is shown in both diagrams in Figure 2. Note at what fraction of a unit cell length $a$, $b$, or $c$ the reference plane cuts the $x$, $y$, or $z$ axes. (If it is not a simple fraction, the stack is of no importance.) Now take the reciprocal of each fraction to obtain the Miller indices. It may happen that the reference plane is parallel to one of the cell axes. In that case the intercept is said to be $\infty$, and the Miller index is $1/\infty = 0$. When algebra is to be done on general values of the Miller indices, the symbols $hkl$ are customarily used.

Reflection of X rays from a stack of planes shows some similarities and some differences compared with what we see reflected in a hand mirror. As with the hand mirror, angle of incidence = angle of reflection.

**Figure 3** Diagram of incident and reflected beam paths for reflection from successive planes in a stack [8]. (Reprinted with permission from IUCr.)

Crystallographers measure these angles between the ray and the plane surface and assign the symbol θ. However, while the hand mirror provides a reflected view whatever its orientation, this is no longer true for a stack of mirrors. Reflected waves from successive planes in the stack must interfere constructively, and this can only happen if the extra distance traversed by waves reflected from the lower mirror, GYH in Figure 3, is equal to an integral number of wavelengths λ. This is the basis of Bragg's law:

$$n\lambda = 2d\sin\theta$$

where $n$ is an integer and $d$ the perpendicular spacing between planes in the stack.

Usually, we work with first-order diffraction so that $n = 1$, and the wavelength λ is most commonly 1.5418 Å for a copper target or 0.7107 Å for a molybdenum target (1 Å = $10^{-10}$ m). Thus, the left-hand side of the equation is constant during an experiment. For a typical crystal

of a small-molecule drug, several thousand stacks of planes have to be set to the appropriate angle θ so that the intensity of reflection can be measured.

This principle leads to the important concept of resolution. To maintain a constant left-hand side, as *d* becomes smaller, sin θ must increase. However, sin θ can never exceed 1, so this determines the minimum spacing between planes that can be observed. This physical limit may not actually be reached due to poor crystal quality or limited availability of measuring time. The smallest spacing between planes actually measured in an experiment is called the *resolution*, and it determines the level of detail that can be observed. Consider the phenyl ring in the amino acid phenylalanine in a protein. The distance across this ring is 2.8 Å, while a carbon–carbon bond length is 1.4 Å. Quite a few protein crystal structures have been measured to 2.8 Å resolution, which would only show the phenyl ring as a vaguely hexagonal blob. Improving the resolution to 1.4 Å should begin to make it possible to see atoms. Advances in cryoprotection of protein crystals and the wider availability of synchrotron beam time have provided increasing numbers of protein crystal structures to resolution even better than 1.4 Å, and "small-molecule" structures of druglike molecules should beat 0.8 Å. The key point is that "high-resolution" is associated with a low number for the *d* spacing, and "low resolution" with a high number.

### 3.4 Relationships between Measured Intensities, Structure Factors, and Electron Density

The measured intensities have to be corrected for background scattering of X rays not due to the diffraction process and by factors relating to the geometry of data collection. The square root of the corrected intensity of reflection from each stack of planes with Miller indices *hkl* is called the *structure factor F(hkl)*. A structure factor will be large if a high proportion of the electron density lies in the planes but small if the electron density is smeared out between planes. Thus, a relationship exists between the full set of structure factors and the electron density at any point within the unit cell. Atoms appear as peaks in a map of electron density. The standard mathematical technique of Fourier transformation, implemented in crystallographic computer programs like the SHELX suite [6, 7], is capable of generating an electron density map from the measured structure factors. However, it requires a key piece of information for each structure factor that is missing from the measurements: the *phase*. The phase of a wave determines whether, at a reference location and a reference time, there is a crest, a trough, or a point in between.

### 3.5 Phase Problem and How It Can Be Solved

There are three main ways to supply the missing phase information, that is, to solve the phase problem. The first method is to set all phases to zero and supply squared structure factors to the Fourier transformation. This produces not a map showing atoms as electron density peaks but rather a map showing vectors between atoms (a Patterson map). For a simple diatomic or triatomic molecule it is not difficult to deduce the locations of the atoms from the pattern of vectors, and some early crystal structures were solved this way. Even for a molecule the size of an aspirin, though, the Patterson map becomes too complicated a molecule to interpret easily. Fortunately, the strength of a vector between two atoms is proportional to the product of their atomic numbers. If just a few atoms are much "heavier" (actually, have a much higher atomic number) than the others, the vectors between them will stand out from the others. This fact makes the *heavy-atom method* feasible. Many early crystal structures of basic drugs were solved as hydrobromide salts, the bromine acting as a heavy atom. In the case of the rubidium salt of benzylpenicillin, the vectors involving rubidium atoms did not stand out enough. However, both the potassium and rubidium salts had the same unit cell dimensions and mode of packing, that is, they were *isomorphous*. In the 1940s Dorothy Hodgkin collected data on both salts and compared the vector maps [11]. Only the vectors involving the cations changed in intensity between the two data sets, and thus *single isomorphous replacement* enabled the heavy atoms to be located. Due to the large number of atoms in a much bigger protein molecule, even single isomorphous replacement may be inadequate, and multiple isomorphous derivatives may have to be made. Fortunately, protein crystals typically contain 40–80% water [12], and it is often possible to diffuse positively and negatively charged ions into the crystal, where they displace water and bind to different sites on the protein molecule without disturbing the packing.

Having located the heavy atom(s), one still needs to find the rest of the structure, which is the drug or protein of actual interest! Starting from the electron density of the heavy atoms alone and running the Fourier transformation backward from electron density to structure factors yields crude values for the magnitude and phase of each structure factor. The roughly estimated magnitudes can be replaced with the measured values while the approximate phases must be kept, for lack of anything better. Running the Fourier transformation forward now produces an electron density map that, thanks to the use of correct structure factor magnitudes, reveals additional atoms. The additional atoms make it possible to calculate a better approximation to the

phases. By such a bootstrapping process the entire structure can be teased out.

This "Fourier refinement" technique for structure improvement is useful for completing the structure starting from approximate phase information, however determined. It also is the basis for the second method of solving the phase problem, *molecular replacement*, which has greatly facilitated the determination of protein structures. For instance, if the structure of an enzyme found in the mouse has been laboriously solved by multiple isomorphous replacement, it is likely that the human enzyme structure will not differ very much. A set of phases calculated from the mouse structure, rotated and translated when necessary, applied to structure factors measured for a crystal of the human enzyme may provide an instant starting point for the location of atoms.

The third, very popular, procedure for phase determination involves the so-called *direct methods*. If the Miller indices *hkl* for three stacks of planes designated 1, 2, 3 have the relation

$$h1 + h2 = h3,\ k1 + k2 = k3,\ l1 + l2 = l3$$

then it is likely though not certain that the phase of reflection from the third stack is the sum of the phases for stacks 1 and 2 (modulo 360°). Thus, knowing a few phases, one can calculate more. Of course, at the start, no phases at all are known. In practice, some phases have to be systematically or randomly guessed, and the right guess will lead to consistent predictions while wrong guesses lead to chaos. By direct methods implementations such as SHELXS [6], it is routine to solve the structures of drugs containing 100 atoms or more, and small proteins are yielding to this approach as well.

### 3.6 Completion of a Structural Model

In the small-molecule context an experienced crystallographer is unlikely to make significant mistakes. Increased automation is encouraging nonspecialists also to determine crystal structures, and most of the time they come up with satisfactory results. However, even in small-molecule crystallography the interpretation of peaks on an electron density map is not always straightforward. While the peak heights ought to be proportional to the number of electrons, someone working hastily may still confuse the location of nitrogen atoms and CH groups in a heterocycle. Chemical common sense and clues such as hydrogen bond acceptance or donation should always be respected.

Another issue concerns hydrogen atoms. Before the 1970s structures were often reported without such atoms. As equipment improved and computing power increased, hydrogen atoms were explicitly located. Sometimes the geometry was strange, but one could be sure a peak had appeared at the site. The modern practice is to place hydrogen atoms in calculated positions based on standard bond distances and angles. The software is very convenient; but given erroneous instructions, it will obediently add nonexistent hydrogen atoms.

The generally lower resolution obtainable with macromolecular crystals increases the dependence on models for the location of atoms. Standard bond lengths and angles in amino acids have been compiled from relevant small-molecule structures for use in refining protein structures [13]. Sometimes the path of the main chain itself may initially be traced erroneously. It is valuable to carry out checks by deleting portions of the molecule and verifying that they come back in an electron density map.

### 3.7 Refinement

Inevitably the atomic positions found in an initial map can be improved so as to give a better fit to the data. Thermal vibration is represented by displacement parameters, assuming that the atom traces out either a sphere (isotropic, one parameter) or an ellipsoid (anisotropic, six parameters). Positions and displacement parameters are refined by a nonlinear weighted least-squares technique. To avoid dominance by a few very large structure factors or degradation of the model by numerous weak ones with a poor signal-to-noise ratio, a weighting scheme is applied to the structure factors. The refinement process does not converge in a single cycle but requires iteration until the shifts in parameters become small, typically <0.01 times their estimated uncertainty.

### 3.8 Anomalous Scattering

When the wavelength of X rays striking an atom is systematically varied, near a certain wavelength called the *absorption edge*, the absorbing power of the atom changes drastically. The scattering of X rays is also affected. Near the absorption edge an electron affected by an X-ray behaves like a damped oscillator, and the phase of the reemitted radiation is changed. The effect on structure factors is that *F(hkl)* is no longer equal to *F(-h,-k,-l)*, and this renders the experiment sensitive to inversion. If a single enantiomer of a chiral drug molecule is present in the crystal, either one form of the structure or its inverse (i.e., left or right hand) will give a slightly better fit to the data and is therefore correct. For greatest certainty all structure factors, both *F(hkl)* and *F (-h,-k,-l)*, ought to be measured and compared; but the Flack parameter [14] has been devised to give

an indication of correctness during refinement of an ordinary data set.

Anomalous scattering has an additional use in macromolecular crystallography. On a synchrotron it is possible to change the wavelength of the X rays to encompass values near to and far from an absorption edge of a heavy atom. The altered scattering power of the heavy atom makes it act like two different elements in the two experiments, thus simulating isomorphous replacement with zero disturbance.

### 3.9 Expressing the Quality of a Crystal Structure Determination

The reader of a crystal structure paper should take note of the quality measures that usually are published. An excellent guide is the *R factor* or *discrepancy index*. For each structure factor, the observed value $F_o$ and the calculated value $F_c$ are compared, and the absolute values of the differences are added up for all the measured data. This sum is divided by the sum of all $F_o$. A small discrepancy between $F_o$ and $F_c$ values confirms both good-quality data ($F_o$) and an appropriate structural model ($F_c$). The perceived importance of the $R$ factor has made it the subject of some cosmetology. It is customary to calculate it only for structure factors that have a value greater than twice their estimated standard deviation, thus eliminating measurements with a poor signal-to-noise ratio. Suppression of any other data gives grounds for suspicion. Expected $R$ factors for small-molecule structures are <0.05 for excellent data and <0.10 for respectably mediocre data. For macromolecular structures much higher values are acceptable. After least-squares refinement the weighted $R$ factor $wR(F^2)$ is also reported. Based on squared structure factors and covering all data, it is more sensitive to discrepancies than the conventional $R$ factor and frequently attains a value more than twice as great.

Of direct relevance to the description of molecular geometry is the standard uncertainty of a typical C–C bond length, which in the small-molecule context should be <0.005 Å for excellent work and should not exceed 0.01 Å except perhaps for bonds affected by problems such as disorder. For macromolecular structures the uncertainty is much greater, usually exceeding 0.1–0.3 Å. Other quality measures that are published in crystal structure papers include the goodness of fit, which should be near 1 if the weights used in refinement are suitable, and the residual electron density, which should be as low as possible. Residuals of ±0.3 electron / $Å^3$ merely indicate harmless noise (larger magnitudes are tolerable near heavy atoms), but significant positive peaks suggest that an atom may have been missed and significant negative regions suggest wrongly positioned atoms. The International Union of Crystallography (www.iucr.org) offers useful software online to help authors check the validity of their results. The multifunctional program PLATON is particularly helpful.

## 4 DETAILED APPLICATIONS AND CASE STUDIES

### 4.1 Determination of Unknown Structures

The work on benzylpenicillin by Dorothy Hodgkin [11], which established the previously controversial β-lactam structure, has already been mentioned. More recent accomplishments include determining the structure of a precursor of the anticancer drug paclitaxel [15] and then paclitaxel itself [16], complicated drugs made from natural products, for which NMR studies had left some issues unresolved. In the macromolecular context studies on human immunodeficiency virus (HIV) protease not only elucidated this previously unknown structure but also provided the springboard for the design of an important class of new drugs.

### 4.2 Salt Selection and Its Importance

Flurbiprofen is a nonsteroidal anti-inflammatory agent with a carboxylic acid group (Fig. 4). Its aqueous solubility is only 0.03 mg mL$^{-1}$ for the free acid. Amine salts of flurbiprofen were evaluated as possible means to attain higher solubility.

In Table 2 it is evident that aqueous solubility for this series with a constant anion does not depend simply on the hydrophilicity of the cation. There must be differences in stability of the crystals formed: crystals of the *n*-butylammonium salt, which has the most hydrophilic cation, must be exceptionally stable to account for its

**Figure 4** Structural formula of flurbiprofen.

**TABLE 2 Aqueous Solubility of (aryl)alkylammonium Salts of Flurbiprofen [17]**

| Ammonium Cation | Solubility (mg/mL) |
|---|---|
| *n*-Butyl | 0.19 |
| *n*-Pentyl | 7.51 |
| *n*-Hexyl | 2.8 |
| Cyclohexyl | 0.37 |
| Benzyl | 2.85 |

**Figure 5** (A) Structures of the cyclohexylammonium cation and flurbiprofen anion showing their interaction in the crystalline salt [17]. (Reprinted with permission from Taylor & Francis, http://www.informaword.com.) (B) Ladder motifs produced by hydrogen bonding between ammonium and carboxylate moieties. For clarity only the carbon atoms directly attached to these groups are shown.

**Figure 6** Structures illustrating steps in the development of potent inhibitors of HIV protease [18]. (Partial figure with permission from AAAS.)

low solubility. The crystalline cyclohexylammonium salt must be more stable than the *n*-hexylammonium variant. Crystals of the cyclohexylammonium salt were of sufficient quality for a structure determination [17] and demonstrated a tidy segregation into nonpolar hydrocarbon domains (Fig. 5A) and hydrophilic, hydrogen-bonded regions that make optimal use of the three hydrogen atoms on the ammonium group (Fig. 5B). Such favorable intermolecular interactions are expected to lower the energy of the crystal and would be lost upon dissolution.

### 4.3 Structure-Based Drug Design

The discovery of new life-saving drugs is arguably the most inspiring application of the entire science of crystallography. HIV protease inhibitors are a notable success story. The study by Lam et al. [18] shows with particular clarity the iterative application of crystallography, modeling, and synthesis, which is conceptually summarized in Figure 6. These authors noted in previously published structures of protease–inhibitor complexes that a structural water molecule, unique to retroviral proteases, accepts two hydrogen bonds from backbone amide groups of the protease and donates two hydrogen bonds to carbonyl oxygen atoms of the inhibitor. They sought a novel inhibitor incorporating a feature that binds to HIV protease like this water molecule, reasoning that with no loss of binding energy it would achieve an entropy gain by freeing the structural water molecule. Furthermore, toxicity should be limited since mammalian proteases lacking such a removable water molecule would provide a poor fit.

The authors began by building a computer model of a fairly simple diol with twofold symmetry docked into the active site, from which they derived a pharmacophore model (Fig. 6C). In this simple pharmacophore hydrophobic groups $P_1$ and $P_1'$ were placed 8.5–12.0 Å apart, each one 3.5–6.5 Å from a common hydrogen bond donor/acceptor. A search of their small-molecule database, a subset of the CSD, revealed a molecule (Fig. 6D) that not only met the criteria but also could position an oxygen atom at the water site. Because the rigid spine of its terphenyl skeleton provided little

opportunity for "tweaking" substituent positions, a 3,4,5-trisubstituted cyclohexanone skeleton (Fig. 6F) was proposed as an alternative offering more chance for development. The carbonyl oxygen atom was expected to accept hydrogen bonds from the protease in the same way as the original water molecule. The 4-hydroxycyclohexanone was conceptually enlarged to a cycloheptanone (Fig. 6G) incorporating two adjacent hydroxyl groups like the original diol. This ring system was altered to a cyclic urea (Fig. 6H) in order to feed extra electron density into the carbonyl oxygen atom and make it a stronger hydrogen bond acceptor. Attention now shifted to the optimal positioning of substituents on the otherwise unoccupied carbon and nitrogen atoms of the ring (Fig. 6I). It was predicted that *4R*, *5S*, *6S*, *7R* stereochemistry would give best complementarity to the protease. After synthesis of such a molecule, small-molecule crystallography confirmed its preferred conformation, and biochemical studies verified tight binding. The research then entered a cyclic phase of synthesis, biochemical evaluation, and crystal structure determination of the drug–protease complex, each cycle providing ideas for the further optimization of the substituents. A total of 10 structures were thus determined, $K_i$ values as low as $0.27 \pm 0.05$ nM were attained, and no inhibition of representative cellular aspartyl proteases was observed at drug concentrations 3000 times the $K_i$ for HIV protease.

On the other hand, imatinib (Gleevec), a "silver bullet" specifically directed against chronic myeloid leukemia, was not and probably could not have been discovered by a structure-based approach. Imatinib blocks the adenosine 5′-triphosphate (ATP) binding site in a kinase encoded by the chimeric Philadelphia chromosome that does not occur in normal cells. Because every cell needs ATP, it is difficult to imagine a committee allocating funds for the design of an ATP blocker. In any case, the structure of imatinib shown in Figure 7 is so different from that of ATP that no analogy would have been spotted.

After its discovery the crystal structure of imatinib bound to its target has been determined [19]. This structure still supplies useful information since it suggests how certain mutations of the target enzyme confer resistance, and how such resistance might be circumvented by structural modifications.

**Figure 7** Structural formula of imatinib.

The diffusion of heavy ions into macromolecular crystals to provide isomorphous derivatives as a means of structure solution has already been mentioned. Because of the high water content of protein crystals, solvent channels through the crystal may actually be wide enough to allow candidate drugs to diffuse [20]. Such soaking experiments do not always work. The extra bulk of the bound drug may cause the crystal to crack. Finding a solvent that dissolves the drug but does not damage the crystal may be difficult. It may be necessary to habituate the crystal to gradually increasing concentrations of the solvent. However, the results can be very rewarding. Pre-formed crystals can be soaked in a solution of the drug, left for hours or days to reach equilibrium, and used for X-ray data collection. With the protein structure remaining largely undisturbed, a trial structure can be rapidly obtained by the molecular replacement method. Thus, the entire process from ligand binding to structure determination can achieve relatively high throughput.

It has even been possible to determine binding constants by this technique [20]. Several soaking experiments in different concentrations of drug are allowed to reach equilibrium. By determining the structure of crystals from each batch, it is possible to refine a fractional occupancy parameter for the drug in its binding site. This value, along with knowledge of the ligand and total protein concentrations, enables a dissociation constant to be calculated.

### 4.4 Use of Databases

By comparing structures of related drug and nondrug molecules, it may be possible to identify structural features required for activity and establish a pharmacophore, even in the absence of the macromolecular target structure. Because of the immense therapeutic importance of the β-lactam antibiotics, such studies were carried out in advance of and in parallel with structure determination of the bacterial transpeptidase that they inhibit. The important moiety in penicillins, cephalosporins, and other β lactams is shown in Figure 8.

**Figure 8** Core structure of a β-lactam antibiotic illustrating the geometrical relationship between important functional groups.

The amide carbonyl carbon atom is attacked by a serine residue from the enzyme, and the nearby carboxylate ion provides an additional anchor point. Two geometric descriptors have been proposed: (1) the Woodward height-of-pyramid *h* measuring the deviation of the amide N atom from the plane of its substituents, which modulates its influence on the carbonyl group, and (2) the Cohen distance *c*, which represents the distance between the carbonyl oxygen and carboxylate carbon atoms. The Desiraju group subsequently showed [21] that consideration of both parameters in tandem improves their reliability, two separate "islands" of activity appearing at low *h*–low *c* and high *h*–high *c*.

Another application [17] involved a series of antimycobacterial carboxamidrazones whose general formula is shown in Figure 9. Because the spread of resistant strains of *Mycobacterium tuberculosis* necessitates long courses of treatment with multiple drugs, discovery of new classes of antimycobacterials would be very advantageous. Although the biological target is unknown, the best drugs in the amidrazone series showed similar minimum inhibitory concentrations [MIC] against the test organism *Mycobacterium fortuitum* to the clinically important drug isoniazid.

Crystal structure determinations on 15 compounds in this series provided structural data on 20 independent molecules. For most molecules an obvious long axis runs through the heterocycle, the central C-N8-N9-C unit, and the aryl ring (Fig. 10). It was postulated that the heterocyclic nitrogen atom accepts a hydrogen bond that anchors the drug in a receptor pocket running parallel to this long axis. With a bulky but short *t*-butyl substituent on Ar, both 2- and 4-pyridyl derivatives are active (MIC 8–16 μg/mL). When Ar is *p*-benzyloxy-*m*-methoxyphenyl with its greater length, the 2-pyridyl derivative is highly active (MIC 4–8 μg/mL) while the 4-pyridyl is inactive. These observations suggest a maximum permissible length and guide synthesis away from overelaboration of the long axis.

Of fundamental concern both for structure-based drug design and, eventually, for crystal structure prediction is the correct assignment of conformation in flexible drug molecules. The structure of a candidate drug molecule from molecular modeling is often calculated for the isolated molecule in a vacuum. If the structure is obtained by small-molecule crystallography, it represents the molecule surrounded by others of like kind. These differing environments could induce different conformations from the one adopted by the drug when bound to its target. The discrepancies were evaluated for a series of 33 small-molecule ligands from a wide variety of drug classes where model, small-molecule, and protein-bound structures were available [22]. The results were discouraging: Conformations differed widely, and root-mean-square (rms) discrepancies increased along with the number of flexible bonds.

More recently, a pair of review articles [23, 24] examined the situation specifically for dihydrofolate reductase (DHFR) inhibitors, for which many structures are available. A particularly well-studied molecule is the antibacterial drug trimethoprim (Fig. 11). Its pyrimidine and phenyl rings are linked by two bonds that can rotate, C4-C5-C7-C1′ and C5-C7-C1′-C2′. Steric hindrance precludes values of 0° or 180° for both together.

In Figure 12 the small-molecule data (squares) fall into two regions identified as I and II. Evidently the macromolecular target selects from this manifold of conformations since the great majority of such structures, whether binary (DHFR with drug) or ternary (DHFR + drug + cofactor) and whether determined by X-ray crystallography or NMR in solution, fall within region I, and the remaining three structures are close to II. These results for trimethoprim and its derivatives

**Figure 11** Structural formula and numbering scheme for trimethoprim.

support a more encouraging conclusion: Although any one small-molecule structure may be unrepresentative of the protein-bound form, the consensus of many structures can be revealing.

Figure 13 shows a very important interaction between inhibitors and DHFRs: a hydrogen-bonded salt link from the protonated N1 and the adjacent 2-amino group of the drug to the side-chain carboxylate group of an active-site aspartate or glutamate residue in DHFR.

**Figure 12** Plot of bridging torsion angles for trimethoprim and its derivatives from small-molecule structures (squares) and bound to DHFR (triangles—ternary complexes with NADPH, circles—binary complexes; open—X-ray data; filled—NMR data) [24]. Crystal structures of small-molecule carboxylate salts enable the geometrical relationships between the protonated drug and the anion to be precisely defined. Comparison of N1 . . . O1 and N7 . . . O2 distances in Figure 14 (data from [23]) shows that N1 . . . O1 is usually the closer contact, presumably representing stronger attraction. Two points that stand apart from the main cluster of data are worthy of some attention. One point represents unusually long (>2.8 Å) values of both distances, N1 . . . O1 and N7 . . . O2. This structure [25], assigned code WOYPIJ in the Cambridge Structural Database, is a trifluoroacetate salt. Diversion of negative charge to the fluorine atoms may lessen the ability of the carboxylate group to attract the cationic drug, leading to longer contact distances. The second outlier, coded ULAXUA [26], has a short N1 . . . O1 distance

**Figure 13** Structural formula and numbering scheme for the hydrogen-bonded salt link between a protonated diaminopyrimidine antifolate drug and a carboxylate anion.

**Figure 14** Scatter plot of N1 . . . O1 and N7 . . . O2 distances in carboxylate salts of protonated diaminopyrimidine antifolate drugs.

**Figure 16** Schematic drawing of the interaction of pyrimidine- and 1,3,5-triazine-based antifolate drugs with counterions and solvent molecules at the 1 and 2 positions [23]. (Reprinted with permission from Taylor & Francis, http://www.informaworld.com.)

**Figure 17** Schematic drawing of base pairing of antifolate drugs at the 3 and 4 positions [23]. (Reprinted with permission from Taylor & Francis, http://www.informaworld.com.)

but a very long N7 . . . O2 (>3.3 Å), suggesting a large relative rotation of the ions.

A mathematical analysis of the geometrical relationship between the diaminopyrimidine (drug) and carboxylate moieties has been published [23]. Starting from a situation where these moieties are coplanar with equal N1 . . . O1 and N7 . . . O2 distances, the axial rotations needed to match the observed arrangements have been calculated. By defining the limits on distortions found in precisely determined small-molecule structures, it should give the drug designer an idea of permissible distortions in the drug–DHFR complex.

The technique of cluster analysis, implemented in the program dSNAP [27], provides an objective classification of similarities and differences. A variety of plot styles can be viewed interactively, but a simple dendrogram usually suffices to show groups of clearly similar structures and to isolate the outliers. Its application to an earlier version of the diaminopyrimidine carboxylate data set discussed previously [23] is shown in Figure 15. Two broad groups are evident; and, as in Figure 14, ULAXUA and WOYPIJ appear as outliers.

The DHFR review [23] went on to catalog the supramolecular hydrogen-bonded interactions of protonated pyrimidine and 1,3,5-triazine-based inhibitors in crystals with a variety of anions, including sulfonate and halide as well as carboxylate ions. The preferred motifs for interaction with oxyanions at the 1 and 2 positions (Fig. 16) are the same in both small-molecule and protein-bound situations.

In the small-molecule structures the unprotonated N3 and the 4-amino group were frequently, though by no means universally, involved in base pairing (Fig. 17), an interaction that does not occur when the inhibitor is bound to DHFR. The motif at the 3,4 positions of an inhibitor bound to DHFR [24] is the same as the second most frequent motif in the small-molecule context (Fig. 18) [23]. Once again, the existence of a large volume of structural data is of key importance. It enables the propensity for intermolecular interactions, as well as features of molecular geometry, to be evaluated.

Although the PDB contains an order of magnitude fewer macromolecular structures than there are small-molecule structures in the CSD, comparison of related macromolecular structures can still be very worthwhile. The recent review of DHFR structures [24] reported the existence of 129 structures obtained from 15 different species as of February 2007. Sequence comparison shows high (75–95%) homology among vertebrate

**Figure 18** Schematic drawing of the second most frequent interaction of antifolate drugs with counterions and solvent molecules at the 3 and 4 positions [23]. (Reprinted with permission from Taylor & Francis, http://www.informaworld.com.)

species but only about 30% homology between vertebrate and bacterial species. Although all DHFR enzymes interact with dihydrofolate, their main substrate, in very similar ways, there are sufficient structural differences at and near the active site to allow selective inhibition to be achieved. Ligand-induced conformational flexibility in loop regions near the active site was an unexpected property of DHFR deduced from structural comparison. It must be considered during the drug design process.

### 4.5 Future Prospects

On the experimental side, the chances of obtaining a usable data set from a sample are improving. Many tedious and time-consuming aspects of crystal growing have recently been automated. Robots can simultaneously conduct crystal-growing experiments on small molecules in a wide variety of solvents with a wide variety of counterions and co-crystal formers. The optimum conditions for growing macromolecular crystals can be systematically investigated. Computer vision systems and computer-controlled spectrometers monitor the success of such efforts. Once the development costs have been amortized, such robotic equipment should become available to less well-funded laboratories. Recently developed microfocus X-ray sources direct narrow intense beams onto crystals, alleviating the minimum size requirements. Even when all attempts to grow adequately sized single crystals of a drug fail, it may still be possible to determine its three-dimensional structure from powder diffraction data. At almost every crystallographic meeting innovative applications of powder diffraction and improved methods for determining structures from powder diffraction data are reported.

The innovation now being applied to crystal structure prediction can also be expected to bear fruit. More groups now take into account the charge distribution on the heteroatoms in drug molecules and its influence on hydrogen bonding, not just treating them as uniform spheres. Prior knowledge from the Cambridge Structural Database is being incorporated into some methods. Kinetic factors are being considered as a reason why certain dense, low-energy, predicted crystal forms do not materialize. Before structure prediction techniques become reliable enough for wide use ab initio, they may link up with powder diffraction by providing trial structures as starting points. Even an occasional correct prediction would be helpful, and the diffraction data would be available to verify its validity.

Indeed it is an exciting time to be applying crystallography to the development of therapeutic agents!

## 1 PEGYLATION

### 1.1 History

The pioneering first steps in PEGylation were taken in late 1970 in the laboratory of Frank Davis of Rutgers University [1]. In late 1970s, PEGylation was first reported by Davies and Abuchowski in two key research papers on albumin and catalase modification [2, 3]. This was an important milestone because at that time it was not conceivable to modify an enzyme while maintaining its activity. Since then, the research on the PEGylation process expanded and developed tremendously [4]. The covalent attachment of polyethylene glycol (PEG) to enzymes, proteins, peptides, and nonpeptides, a process known as PEGylation, has received increased attention [5] nowadays.

Abuchowski et al., [2] altered the immunological properties of bovine serum albumin (BSA), which was achieved by the covalent attachment of PEG. With this achievement, the exploration of PEG chemistry started [6].

### 1.2 Definition

Different researchers have defined PEGylation in their own words. PEGylation involves the masking of the surface of proteins and peptides by covalent coupling with soluble PEG [1]. It is a method for optimizing pharmacokinetic and pharmacodynamic properties of therapeutic small drug molecules such as peptides and proteins [7].

Thus, it can be concluded that PEGylation is the modification of the surface properties of proteins and peptide or nonpeptide molecules via covalent attachment using a chemical modifier, PEG, either alone or in combination with other moieties. PEGylation has been exploited to increase the half life ($t_{1/2}$), solubility, stability and decrease of the immunogenicity, and toxicity of enzymes, proteins, peptides, and nonpeptide molecules.

### 1.3 PEGnology

PEGnology, as the name indicates, is the study of the modifications of proteins, peptides, or nonpeptides by associating them with PEG [8]. Frank F. Davis, of Rutgers University, New Jersey, is known as "father of PEGnology." While browsing in medical journals, he came across an article that explained how physicians infused a solution containing a mild surfactant, a block copolymer of PEG and polypropylene glycol into the blood of patients undergoing major vessel surgery in order to prevent the formation of lipid embolisms [8]. This was when he focused on PEG [8] and started his work with methoxy PEG.

## 2 PEGYLATION OF THERAPEUTIC AGENTS

### 2.1 Proteins and Peptides

Many differences exist among proteins/peptides and conformational low-molecular-weight (MW) compounds,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

which may affect their predicted stability profiles. The distinction between peptides and proteins is somewhat arbitrary. Typically, peptides contain fewer than 20 amino acids and proteins contain 50 or more amino acids, between these two categories are polypeptides, which contain about 20–50 amino acids. Polypeptides consist of regularly repeating amino acid units with distinctive side chains that interact with each other to contribute to the three-dimensional structure of the protein [9]. In terms of MW, peptides have a MW less than 5000 Da and proteins have a MW more than 5000 Da.

***Primary Structure*** The sequence of covalently bonded amino acids in the polypeptide chain is known as the primary structure. The primary structure of proteins is determined genetically by the sequence of nucleotides in deoxyribonucleic acid (DNA). Once a polypeptide chain is formed, there is only one residue with a free amino group and only one residue with a free carboxylic group [10].

***Secondary Structure*** The turns and loops of the polypeptide chain constitute the secondary structure. The α helices and the β sheets are the common conformations of the secondary structure. In the α helix, a single protein chain twists like a coiled spring. Each turn contains 3.6 amino acid residues, with the side chain pointing out from the helix. All NH and CO groups are hydrogen bonded except the first NH and the last CO group, which occur at the end of helices. Therefore, the ends of helices are polar and are likely to be at the surface of protein molecules [10].

In the β-sheet conformation, the protein backbone is nearly fully extended. The β sheets can be either parallel or antiparallel. In the parallel β sheet, two or more peptide chains align their backbone in the same direction. The antiparallel β sheet has adjacent chains having parallel but opposite orientations. A protein can contain about 30% of the residues in α helices and 30% in β sheets and the rest in other conformations such as the random coils or β bends. A fully extended polypeptide chain of about 60 residues may be about 200 long, but the folded globular protein may actually be just 30 in diameter [10].

***Tertiary Structure*** The tertiary structure of protein is the overall packing in space of the various elements of the secondary structure. Protein folds in a highly specific manner, but it is believed that the specific folding is determined by the amino acid sequence or the primary structure of the protein. The overall shape is spherical; polar groups are on the surface, and hydrophobic groups are buried in the interior; the interior is closely packed. Guided by these rules, protein folds into a unique structure [11].

The forces that may stabilize the folded structure of proteins may be covalent or noncovalent. Disulfide bridges provide a covalent linkage that can hold together two chains or two parts of the same chain. The disulfide bonds are very hydrophobic compared to the thiol groups. The noncovalent forces that can stabilize proteins include hydrogen bonding, salt bridges, and hydrophobic interactions between the amino acids. Typically, a protein would have maximum conformational stability at its isoelectric point, but this may shift because of the presence of counterions [12].

***Quaternary Structure*** The quaternary structure of a protein refers to the specific association of separate protein chains (subunits or monomers) to form a well defined structure. The subunits are held together by noncovalent forces such as hydrophobic interactions, hydrogen bonds, or van der Waals interactions. Protein–protein associations usually involve the more hydrophobic portions on the surface of a molecule [13]. Normally, the hydrophobic residues are buried in the interior, but they can also be closer to the exterior. This is especially true when the protein has a quaternary structure because the subunits form part of a larger aggregate with geometry that influences the location of the hydrophobic residues, such as tryptophan in α crystallin.

The use of proteins and peptides as human therapeutics has expanded in recent years due to: (1) the discovery of novel peptides and proteins, (2) a better understanding of the mechanism of action in vivo, (3) improvements in expression or synthesis of proteins and peptides that closely resemble human proteins and peptides, (4) improvements in formulation or molecule-altering technologies that have the ability to deliver polypeptides in vivo with improved pharmacokinetic and pharmacodynamic properties [14].

Currently, there are more than 100 recombinant proteins (RP) in phase I clinical trials or beyond, and several dozen have received Food and Drug Administration (FDA) approval. The available delivery methods for proteins can critically be evaluated by considering ease of manufacturing, impact on conformational stability and biological activity, bioavailability, and toxicity. Therefore, the formulation design, which ensures an efficient and a safe delivery of proteins and peptides in a conformationally stable and biologically active form, is the key to commercial success of current and future biotechnology products [15].

Many biopharmaceuticals have problems that are typical of polypeptide therapeutics, including short circulating half-life, immunogenicity, proteolytic degradation, and low solubility [14]. Several strategies have emerged as ways to improve the pharmacokinetic and pharmacodynamic properties of biopharmaceuticals.

These include (1) manipulation of amino acid sequence to decrease immunogenicity and proteolytic cleavage, (2) fusion or conjugation to immunoglobulins and serum proteins, such as albumin, (3) incorporation into drug delivery vehicles for protection and slow release, and (4) conjugating natural or synthetic polymers [3, 16–18]. Those in the biomedical, biotechnological, and pharmaceutical communities have become quite familiar with the improved pharmacological and biological properties that are associated with the covalent attachment of PEG to therapeutically useful polypeptides. For instance, PEG conjugation shield antigenic epitopes of the polypeptide, thus reducing clearance by the reticuloendothelial system (RES), recognition by the immune system, and reduced degradation by proteolytic enzymes. PEG conjugation also increases the apparent size of the polypeptide, thus reducing renal filtration and altering biodistribution [14]. The main modifications exerted by PEGylation include steric hindrance, changes in conformation, changes in electrostatic binding properties resulting in an increase in polypeptide molecular size, and the shielding of its surface from the approach of proteolytic enzymes, antibodies, or antigen-processing cells [7]. Perhaps the most significant modification to improve circulatory $t_{1/2}$ of proteins is PEGylation [19].

In the early 1990s, Altus Biologics introduced cross-linked enzyme crystals, which were dimers of common enzymes hardwired together by covalent chemical bonds [19]. It is also a feasible technique to alter the membrane disruption behavior of a molecular carrier by manipulating its hydrophobic stabilization [20].

PEGylation significantly improves several classes of protein drugs, such as enzymes, cytokines, and antibodies. Table 1 compiles the most important examples of protein conjugates, exploiting the advantages of PEGylation and PEG derivatives that are useful therapeutically. In general, the improvements are an increased retention time in the body, a reduction of immunogenicity, and increased stability toward metabolic enzymes [4].

Unfortunately, the PEGylation of proteins is often accompanied by loss of biological activity. However, this is compensated for by the prolonged body residence time as a result of the increased stability and higher hydrodynamic volume. A typical example is the PEGylated α interferon, which retains only 7% of the antiviral activity of the native protein but still shows a greatly improved performance in vivo, compared with the unmodified enzyme because of improved pharmacokinetics [21]. A further instructive case comes from the PEGylation of the tumor necrosis factor (TNF) and its lysine-deficient mutant proteins, as reported by several laboratories [22–24]. It was demonstrated that body residence time, PEG mass and shape, and the stability of PEG–protein bonds are all important factors for the antitumor activity, probably because they play a role, in this specific case, in releasing the native protein [25] or in maintaining the activity of the protein inside the tumor mass [4].

Many approaches for protein delivery have been examined, including protein entrapment in insoluble matrices [1] and liposomes and immobilization onto polymer resins for use with extracorporeal shunts through which blood could flow [26]. By far the most successful approach that has been used to mask the protein surface by covalent coupling of soluble PEG is PEGylation [1]. This approach has been applied successfully to develop various marketed therapeutic protein formulations such as Amgen's Neulasta (Pegfilgrastim), a PEGylated version of G-CSF (granulocyte colony-stimulating factor) used to boost white blood cells, and Roche's Pegasys, PEGylated α interferon for treating hepatitis. In both cases, PEGylation has improved the efficacy of the protein and reduced the dosing. Most importantly, PEGylation demonstrated

**TABLE 1 Approved PEG Conjugates [4]**

| PEG Conjugates | Type of PEGylation | Disease |
|---|---|---|
| PEG–asparaginase (Oncaspar) | Random, linear PEG | Acute lymphoblastic leukemia |
| PEG–adenosine deaminase (Adagen) | Random, linear PEG | Severe combined immunodeficiency disease (SCID) |
| PEG–interferon-α2a (Pegasys) | Random, branched PEG 40 kDa | Hepatitis C |
| PEG–interferon-α2b (PEG–Intron) | Random, linear PEG 12 kDa | Hepatitis C and clinical trials for cancer, multiple sclerosis, HIV/AIDS |
| PEG–G–CSF (Pegfilgrastim, Neulasta) | Selective, linear PEG 20 kDa | Treating of neutropenia during chemotherapy |
| PEG–growth hormone receptor antagonist (Pegvisomant, Somavert) | Random, linear PEG 5 kDa (genetic modified protein) | Acromegaly |

that chemical modification can make complex protein drugs more effective [19].

### 2.2 Drugs

Common problems encountered with the use of small molecular weight drugs especially the antitumor agents, are their low solubility, rapid excretion, and untargeted biodistribution [4]. PEGylation can address all these factors. Increased solubility, modification of pharmacokinetics, and targeting for important drugs such as taxol, camptothecin, *cis*-platinum, and doxorubicin had been described only after the introduction of PEGylation as a new chemical/biochemical modification technique [27]. The conjugation chemistry of nonprotein drugs faces fewer problems because of the reduced number of functional groups present on the molecule, absence of conformational constraints, and easier purification and characterization steps for the drug–polymer conjugates [4]. For small-molecule drugs many researchers have exploited PEGylation for conferring a passive targeting to solid tumors, by enhancing permeability and retention effects [28], or simply by improving the drug's pharmacokinetic profile by slowing the drug clearance from the body [4].

A general problem encountered in PEGylation of small–molecular weight drugs is the low loading of the polymer, which possesses only one or two activated hydroxyl terminal groups that can be activated [29]. To overcome this limitation, some research groups have proposed the construction of dendrimeric structures at the level of the polymer termini, obtaining PEG dendrons, called forked PEGs. The implementation of the number of active groups is reached by using branching molecules, such as bicarboxylic amino acid, which allows an increase in the drug–polymer loading ratio [29].

Doxil is a representative commercialized PEGylated liposomal formulation of doxorubicin [30]. In this formulation, a PEGylated liposome, that is, STEALTH liposome, enhances therapeutic effect and decreases serious side effects such as cardiotoxicity of doxorubicin by improving its biodistribution [31].

### 2.3 Gene Delivery through Nonviral Polymeric Vectors

Gene therapy is a technology employing a gene as a therapeutic agent to treat a disease. The potential goals of gene therapy include replacement of an inactive gene, reactivating inactive gene, turning off gene causing disease, as observed in oncogenes, turning on further naturally protective genes, or adding a gene characteristic to cells, such as increased susceptibility of cancer cells to chemotherapeutic drugs [32]. Thus, it is important to develop a technology and methodology of a drug delivery system to enhance the level of protein expression accompanied with gene transfection [33]. The objective of gene therapy is to allow a gene to express the coded protein in the target cells and consequently to treat disease by the protein secreted from transfected cells.

For instance, gelatins have been grafted with PEG (e.g., PEG-cationized gelatin) to function as a nonviral gene carrier [34]. Following intravenous injection, the PEG-introduced gelatin was retained in the blood circulation for a longer period than the original gelatin [34]. It is likely that gelatin is covered with the PEG molecule and protected from the enzymatic attack and exclusion by RES [33]. The presence of PEG molecules for the PEG-cationized gelatin–plasmid DNA complex protects the plasmid DNA from the enzymatic attack because of the "stealth effect" of PEG [35]. The level of gene expression was significantly increased when the PEG-cationized gelatin–plasmid DNA complex was intramuscularly administered and compared with the injection of plasmid DNA solution. Therefore, PEG-cationized gelatin is a promising nonviral gene carrier to enhance gene expression in vivo [33].

A variety of nonviral polymeric gene vectors have received much attention in the past [36–38] for the delivery of genetic materials to the targeted cells in an effective and safe manner. Especially, the polyplexes formed by the electrostatic interaction between plasmid DNA (pDNA) and polycations have been designed to condense pDNA by shielding its negative charges, protect pDNA from rapid nucleolytic degradation, and facilitate its cellular uptake in order to achieve effective gene delivery [39, 40]. When the complex of a plasmid DNA with a nonviral gene carrier is given to cells or injected into the body in the solution form, the plasmid DNA is rapidly and readily degraded and inactivated by enzymes or cells. As one practically possible way to minimize the enzymatic degradation of plasmid DNA, the surface of the plasmid DNA can be modified with PEG or PEG-like polymers [33].

A typical PEGylated polyplex is a core–shell type of micelle (polyplex micelle) formed through the electrostatic interaction between pDNA and PEG-*block*-polycation copolymers. One of the advantages of polyplex systems is the possibility of various structural modifications to improve the stability and transfection efficiency of the polyplexes. Among such modifications, PEGylation of polycations is a promising way to realize systemic gene delivery due to the improved stability of polyplexes in biological media [33]. Kakizawa and Kataoka [41] have reported

delivery systems of genes and related compounds with PEG-based polymer micelles. The research data revealed that the formation of PEG-based polymer micelles protected the plasmid DNA from DNase degradation [33].

Polyplex micelles have also been demonstrated to show high colloidal stability under biological media and substantial transfection activity against various cells even after preincubation with serum proteins [42, 43]. Moreover, polyplex micelles showed prolonged blood circulation and in vivo gene transfer to liver [40, 44]. Polyplex micelles from PEG-*block*-poly(*N*-substituted asparagine) copolymers having the *N*-(2-aminoethyl)-2-aminoethyl group in the side chain, for example, [45] showed efficient and nontoxic transfection to several primary cells including endothelial and smooth muscle cells and, thus, is expected to be a potent nonviral vector for in vivo gene delivery [45].

## 3 POLYETHYLENE GLYCOL

PEGs comprise a series of low-to-medium MW, wholly synthetic water-soluble polymers [46]. Chemically, they can be regarded as polyether diols, made by the stepwise addition of ethylene oxide to water or ethylene glycol starters to form long, linear chains of oxyethylene ($-CH_2CH_2O-$) units having primary hydroxyl groups at each end. Depending upon chain length, they range in physical form at room temperature from transparent to white viscous liquids (MW 200–700 Da), through waxy semisolids (MW 1000–2000 Da), to hard, waxlike solids (MW 300–20,000 Da and above). All PEGs are completely soluble in water, very low in toxicity, quite bland, and nonirritating. In addition, they possess good solvent action, good stability, and good lubricity. This unusual combination of properties has enabled them to find a very wide range of commercial applications in fields such as ointments, suppositories, cosmetic creams, lotions, and dressings; paper coating lubricants; softeners and modifiers; metal working lubricant detergent modifiers; and wood impregnants [46]. PEG is nontoxic, nonimmunogenic, nonantigenic, highly soluble in water, and FDA approved [4].

### 3.1 PEG Moiety Properties

***Chemical Nature of PEG*** All the PEG molecular chains, regardless of length, are in fact diols, with primary hydroxyl groups at each end. Thus, they can enter into all the chemical reactions characteristic of aliphatic hydroxyl groups, for example, esterification, urethane formation, cyanoethylation, and the like. Commercially, the most useful chemical derivatives of the PEGs are the fatty acid mono and diesters, which are valuable as emulsifiers, detergents, softeners, and lubricants [46]. In its most common form, PEG is a linear or branched polyether terminated with hydroxyl groups and having the general following structure [14]:

$$HO-(CH_2CH_2O)_n-CH_2CH_2-OH$$

***Synthesis of PEG [14]*** PEG is synthesized by anionic ring-opening polymerization of ethylene oxide initiated by nucleophilic attack of a hydroxide ion on the epoxide ring. Most useful for polypeptide modification is monomethoxy PEG (mPEG) having the following general structure:

$$CH_3O-(CH_2CH_2O)_n-CH_2CH_2-OH$$

***Synthesis of mPEG [14]*** mPEG is synthesized by anionic ring-opening polymerization initiated with methoxide ions. Commercially available mPEG contains a considerable amount of diol PEG due to the presence of trace amounts of water during polymerization. This diol PEG has relatively high MW due to polymerization at both ends of the polymer. The amount of diol PEG can exceed 15% of the composition of mPEG.

***Physical Nature of PEG*** A number of grades of PEGs are commercially available. They are listed in Tables 2 and Table 3. When blends of different grades of PEG are being considered, it should be realized that the

**TABLE 2 A Properties of Liquid PEGs**

| Grade Number | 200 | 300 | 400 | 500 |

| Water solubility (g/100 mL) | ~74 | ~70 | ~62 | ~53 | ~50 |

average molecular weight of the blends must be calculated on the basis of the number of moles of each grade, not the actual proportion by weight. For example, an equimolar blend of grades PEG 1000 and PEG 4000 would have an average MW of 2500 Da, and would correspond to a 20:80, PEG 1000:PEG 4000 mixture on a weight basis. The 50:50 weight basis mixtures of these two would correspond to a 4:1 mixture on a molar basis and would have an average MW of 1600 Da [46].

*Solubility in Water* All grades of PEGs are soluble in water. Aqueous solutions of higher MW grades may form gels [47].

*Solubility in Organic Solvents* PEGs are soluble in most of the organic solvents with higher polarity, such as alcohols, ether alcohols, glycols, esters, ketones, aromatic hydrocarbons, nitroparaffins, and the like. They are neither soluble in the aliphatic or cycloaliphatic hydrocarbons nor in other solvents of low polarity [46]. In addition, the PEGs are also soluble in a number of liquids not usually regarded as solvents, such as the lower aldehydes, amines, organic acids and anhydrides, and polymerizable monomers. They are not soluble in vegetable or mineral oils or similar liquid compounds. The individual PEGs differ considerably in their solubilities, with the lower-molecular-weight grades being generally much more soluble than the higher grades. Often, raising the temperature high enough to melt the solid PEGs greatly improves their solubility [46].

*Hygroscopicity* The ability of the lower PEGs to take up and retain moisture from the atmosphere, coupled with their good permanence and good plasticizing action for other substances, makes them industrially useful as humectants for a variety of hydrophilic products [46].

***Toxicological Properties*** PEG shows little toxicity and is eliminated from the body intact either by the kidneys (for PEGs < 30 kDa) or as digestive wastes (for PEGs > 20 kDa). PEG is rapidly cleared in vivo without structural change and clearance is dependent on molecular weight [14]. PEG lacks immunogenicity, and antibodies to PEG are generated in rabbits only if PEG is combined with highly immunogenic proteins. No reports were found on the generation of antibodies to PEG under routine clinical administration of PEGylated proteins. PEG is only weakly immunogenic even at high molecular weights [14]. However, under extreme experimental conditions, antibodies to PEG have been generated in animals as a result of the injection of PEG–protein conjugates [48]. Antibodies to PEG have also been generated when attached to a highly immunogenic molecule under an immunization protocol with Freund's adjuvant [14].

Under the Food Additives Amendment to the Federal Food, Drugs and Cosmetics Act, the *Food Chemicals Codex* grades of the PEGs are cleared for various direct and indirect food additive uses, provided that the amounts used do not exceed those required to produce the intended effect. The FDA has approved PEG for use as a vehicle or base in foods, cosmetics, and pharmaceuticals, including injectable, topical, rectal, and nasal formulations [48]. Under EPA (Environmental Protection Agency) regulations, PEGs are exempted from any requirement of residue tolerance when used as inert ingredients in pesticide formulations that are applied to growing crops or harvested agricultural products [46].

### 3.2 Polyethylene Glycol versus Polyethylene Oxide

PEGs are viscous liquids or waxy solids with a MW less than ~25,000 Da [49]. The PEGs should be distinguished from high and very high MW polymers of ethylene oxide, which are also water soluble [50]. These high MW polymers of ethylene oxide are commonly known as poly ethylene oxide (PEO) [51]. PEO resins are made commercially by the catalytic polymerization of ethylene oxide in the presence of metallic catalyst systems. They are available with average molecular weights from 200 to $7 \times 10^6$ [49] and form strong, thermoplastic films [50]. They are represented by the formula $(OCH_2CH_2)_n$

in which *n* represents the average number of oxyethylene groups (~2000 to more than 100,000).

### 3.3 PEG Reagents for Protein Modification

Protein modification reagents that incorporate repeating ethylene oxide/ethylene glycol subunits onto the surface of a protein are often referred to as PEGylation reagents. Some important modification reagents are discussed next.

***Alkylating PEG*** This is a convenient way for conjugation when the amino positive charge is critical for the retention of biological activity. Alkylating PEG derivatives maintain the charge of the native protein in the final conjugate [4]. These products do not modify the charge of amino residues [52]. One of the example, that is, PEG-aldehyde, gives a permanent linkage after Schiff base formation followed by cyanoborohydride reduction (Fig. 1A). However, the reaction rate for the Schiff base formation is relatively low (approx. 24 h), thus leading to inactivation of labile molecules. The reaction pH is critical for selectivity; α-amino terminal modification can be achieved at around pH 5 [53]. PEG-tresyl chloride activation is an alternative method to maintain positive charge [54] (Fig. 1B). However, the chemistry of conjugation and the conjugation products are not unique and well defined [55]. The use of epoxy PEG has been used, but, again, as with PEG-aldehyde, the reactivity is low and, furthermore, the specificity is not certain since hydroxyl groups may also react (Fig. 1C). The popular alkylating PEG derivatives have been enlisted in Table 4.

***Acylating PEGs*** These are the PEG derivatives that, after amino coupling, lead to a loss of positive charge in the final conjugate with respect to starting protein [4].

**Figure 1** Alkylating PEGs: (A) PEG aldehyde: Best reaction takes place with α- and ε-amino groups in protein at neutral or mild alkaline pHs, while good selectivity for the α-amino terminal aminoacid at pH 5–6 was found. (B) Tresylated-PEG: Best reaction takes place with amines around pH 8 and low temperature. The positive amino charge is maintained. The reaction rate is dependent upon the properties of the peptide, but doubts remain on the structure of the reaction products. (C) PEG epoxide: Reaction at high pH 8.5–9.5, is preferred for amino conjugation, although binding to hydroxyl, imidazole and thiol groups also may take place [52].

**TABLE 4 Alkylating PEGs [4]**

| Structure | Alkylating PEGs | Properties |
|---|---|---|
|  | PEG–aldehyde | A two-step reaction; the first product (a Shiff base) is reduced by $NaCNBH_3$. When the coupling reaction is carried out at low pH, i.e., 4.5–5, it labels only the α-amino group. |
| $PEG–O–SO_2–CH_2CF_3$ | PEG–tresyl or tosyl | Not much used because the chemistry leads to a mixture of products. |
|  | PEG–dichlorotriazine or cholortriazine | Now they are abandoned for therapeutic application because of their toxicity. |
|  | | |
| | PEG–epoxide | Slowly reactive, rarely used. |

**Figure 2** Acylating PEGs: (A) Activated alkyl acids: These compounds are highly reactive toward amino groups, but the reaction rate may change significantly from the X structure. (B) PEG-*p*-nitrophenylcarbonate (B1) and PEG–trichlorophenylcarbonate (B2): The reaction rate is much slower than the OSu-activated carboxylate–PEG. Carbamate derivatives are obtained. (C) PEG–oxycarbonylimidazole (C1) and PEG–benzotriazole carbonate (C2): Both reagents yield carbamate linkages with amino groups, but with different reaction rates [52].

Most of these are hydroxysuccinimidyl esters (–OSu) of carboxylated PEGs (Fig. 2A) [52]. The distance between the active ester (–COOSu) and the last PEG ether can vary in different available products by up to four methylene units, and this has profound influence on the reaction toward amino groups as well as toward water. As an example, the $t_{1/2}$ hydrolysis rate of PEG–O–$CH_2$–$CH_2$–$CH_2$–COOSu is 23 h, while that of PEG–O–$CH_2$–COOSu is 0.75 h [52].

In another acylating mechanism, the terminal PEG hydroxy group is activated by chloroformates or carbonylimidazole. PEG-p-nitrophenylcarbonate or PEG-trichlorophenylcarbonates exhibit lower reaction rates than the –OSu-activated PEGs, and this property allows exploitation of different reactivity among the amino groups of the macromolecule by stopping the reaction at the desired time of modification. In this way some selectivity in the conjugation based on amino group availability can be achieved. Furthermore, reactions in aqueous-organic solvents are also feasible. There is an interesting difference between these two carbonate-activated PEGs: The first one has a pale yellow color, whose intensity increases with the conjugation reaction for the formation of phenol as a leaving group, while the second is a colorless product [52].

A urethane linkage with amino groups is also obtained with other electrophilically activated PEGs. Among these are PEG-oxycarbonylimidazole [56] and PEG-benzotriazole carbonate (Fig. 2C). The first one is characterized by a lower reaction rate as compared to choloroformates, while the second one is very reactive, although less than the succinimidyl-activated carboxyl PEGs [52]. Some acylating PEG derivatives are listed in Table 5.

To avoid the mixtures of PEGylated products, the evolution of PEGylation chemistry has also allowed site-specific amino modification, thus helping the purification and characterization procedures. It is also feasible to protect the active site of enzymes or the recognition area of proteins by carrying out the PEGylation in the presence of an inhibitor, a substrate, or a specific ligand, with the aim to cover the reactive groups close to sensitive areas. These ligands might be free in the reaction solution or linked to an insoluble resin. In the latter case, not only the binding site but also its surroundings are protected from conjugation [4].

***PEG with Amino Acid Arm*** The presence of an amino acid or peptide arm between PEG and the attached macromolecule gives several advantages due to the variability of properties that may be introduced using a suitable amino acid or peptide. For the convenience of synthesis, the amino acid or peptide can be linked through its amino group by urethane linkage to PEG, while the carboxyl group, properly activated, is bound to the amine of the macromolecule [52] (Fig. 3). Among these arms, norleucine is of interest for the advantage in analysis of PEGylated proteins. A second modification is the so-called branched PEG or PEG2. This PEG derivative is characterized by two linear PEG chains linked together through two functions of a trifunctional spacer, while the third function is used to bind the protein. Lysine is the trifunctional amino acid spacer and the two PEG chains are linked to its α and ε amino groups while the carboxylic group is activated as –OSu for protein binding (Fig. 4). This PEG has the advantage of a lower inactivation of the enzymes during conjugation. Furthermore, due to its "umbrella-like" structure it is more elective in protecting proteins from proteolysis, in the approach of antibodies, and in reducing immunogenicity [52] (Fig. 4).

***Branched-Chain PEG*** In addition to the linear structure of the PEG molecule shown in Figure 5, branched structures have been proved useful for protein and peptide modification. The first branched PEG structure, 2,4-bis(methoxyPEG)-6-chloro-*s*-triazine (mPEG-2

**TABLE 5 Acylating PEGs [4]**

| Structure[a] | PEG–Carboxilates | Properties |
|---|---|---|
| PEG–O–(–$CH_2$–)$_n$–C(=O)–OSu | Several PEG derivatives with one or more $CH_2$ groups between the PEG and the carboxylic group | The carboxylic group is activated as *N*-hydroxy succinimidyl ester, imidazole or benzotriazole. The kinetic rate of conjugation depends on the numbers, and eventual ramification of $CH_2$ groups linked to the carboxyl group. |
| PEG–O–C(=O)–$CH_2CH_2$–C(=O)–OSu | PEG–succinimidyl succinate | The ester bond between succininc acid and PEG is easily hydrolyzed |
| PEG–X–C(=O)–OSu | PEG–amino acid-succinimidyl ester | Norleucine (Nle) or β-Alanine (βAla) as amino acid moiety allows an easy quantification of the number of linked PEG chains by amino acid analysis. |
| PEG–(–X–)$_n$–C(=O)–OSu | PEG–peptide-succinimidyl ester | The Met-Nle or Met-βAla allows the removal of PEG by CNBr treatment for an easy localization of PEGylation site. Lysosomal cleavable sequences, as H-Gly-Phe-Lue-Gly-OH, allow the release of the bound drug inside the cell. |

| Structure[a] | PEG–Carbonates | Properties |
|---|---|---|
| PEG–O–C(=O)–O–C$_6H_4$–$NO_2$ | PEG–*p*-nitrophenyl carbonate | Slowly reactive, yield a urethane linkage with amine. |
| PEG–O–C(=O)–O–N (benzotriazolyl) | PEG–benzotriazolyl carbonate | Slowly reactive, yield a urethane linkage with amine. |
| PEG–O–C(=O)–O–C$_6H_2$(Cl)$_3$ | PEG–2,3,5-trichlorophenyl carbonate | Slowly reactive, yield a urethane linkage with amine. |
| PEG–O–C(=O)–OSu | PEG–succinimidyl carbonate | Slowly reactive, yield a urethane linkage with amine. |

[a]Su, succinimide; X, amino acid linker.

**Figure 3** PEG amino acids: A variety of properties may be conveyed to the PEG conjugate using different amino acids or peptides. Examples may be: Nle for analytical purposes, $^{14}C$ or tritium-labeled Gly for pharmacokinetic studies, Trp for fluorescence labeling, Lys for branching, Met-Nle or Met-bAla for PEG removal by BrCN treatment [52].

**Figure 4** The "umbrella-like" structure of branched PEG explains the higher capacity in rejecting approaching molecules or cells as compared to linear PEG of the same size [52].

**Figure 5** Branched PEG (PEG2) based on PEG-triazine [14].

**Figure 7** Linear forked PEG (Y is a group having a carbon branching moiety and X is a molecule, linker, and/or a functional group) [14].

**Figure 6** Branched PEG (PEG2) (X is a molecule, linker, and/or a functional group) [14].

**Figure 8** Branched forked PEG (Y is a group having a carbon branching moiety and X is a molecule, linker, and/or a functional group) [14].

chlorotriazine), was based on a triazine core and synthesized by Inada et al., as shown in (Fig. 5) [14].

Yamasaki et al., first synthesized a more useful branched PEG structure, based on a lysine core. A highly purified branched PEG or PEG2 (Fig. 6) was constructed by Veronese et al., using two linear PEG–BTC (PEG–benzotriazole carbonate) chains linked to the α- and ε-amino groups of lysine. This construct allowed a large molecular weight (upward of 60 kDa) and highly pure PEG to be synthesized with a single reactive end group [14].

PEG2 turns out to be a more effective protein PEGylation reagent because of its unique characteristics when compared to linear PEGs. For example, PEG2 attached to proteins "acts" to be much larger than a corresponding linear mPEG of the same MW. This structure of PEG also has the advantage of adding two PEG chains per attachment site on the protein, therefore reducing the chance of protein inactivation [14].

Another branched PEG is the forked PEG. Instead of having a single functional group at the end of two PEG chains, as with PEG2, forked PEG has two reactive groups at one end of a single PEG chain (Fig. 7) or branched PEG (Fig. 8).

*[Methyl PEG$_{12}$]$_3$–PEG$_4$–NHS Ester* The amine-reactive, methyl-capped PEO-containing modification reagent is characterized by its triply branched, $(PEO)_{12}$-containing chains built off a $(PEO)_4$ stem that terminates in an *N*-hydroxyl succinimide (NHS) ester [57].

A branched (methyl-PEO$_{12}$)$_3$–PEO$_4$–NHS can efficiently cover the surface of a protein. Each branched

reagent contributes three, long polyoxyethylene glycol chains per protein modification site. These chains impart all the benefits known to be associated with proteins modified by PEG-containing reagents, including improved stabilization, with potentially fewer sites requiring modification.

(Methyl-$PEO_{12}$)$_3$–$PEO_4$–NHS ester is unique because the branched spacers are discrete with respect to the number of PEG groups indicated. The reagent is synthesized as a homogeneous compound of defined molecular weight, characterized by discrete chain lengths, providing a greater ability to optimize and characterize surface protein modifications. Each reagent contains a single NHS ester group that reacts with primary amines (e.g., ε-amino groups of lysine and the amino terminus of proteins) at pH 7.0–9.0 to form covalent amide bonds. Typically, PEGylation reagents are a heterogeneous mixture composed of a distribution of chain lengths in proximity to a specific MW or number of PEG subunits [57].

*[Methyl-$PEG_{12}$]$_3$–$PEG_4$–maleimide* This sulfhydryl-reactive, methyl-capped PEO-containing modification reagent is similar to that of amine-reactive reagent except the $PEO_4$ stem that terminates in a sulfhydryl-reactive maleimide group [57].

Since SH groups, occurring naturally or as reduced disulfides, appear at a substantially lower frequency than ε-amino groups, for example, in protein sequences, a branched (methyl-$PEO_{12}$)$_3$–$PEO_4$–maleimide increases the effectiveness of the PEG modification. At each –SH locus modified with this reagent, three, long polyoxyethylene glycol chains are covalently inserted. These branched chains can impart the benefits associated with proteins PEGylated with single-chain maleimide reagents, including improved stabilization, with fewer sites requiring modification.

(Methyl-$PEO_{12}$)$_3$–$PEO_4$–maleimide contains a single maleimide group that reacts with available sulfhydryl (–SH) groups on proteins and peptides at pH 6.5–7.5 forming a covalent thioether bond. The maleimide group is highly specific to free –SH group being 1000× more reactive at pH 7, as compared to primary amines. The properties of [methyl-$PEG_{12}$]$_3$–$PEG_4$–NHS ester and [methyl-$PEG_{12}$]$_3$–$PEG_4$–maleimide are listed in Table 6.

### *Linear PEG*

*Methyl-$PEG_n$–NHS Ester (n = 4, 8, 12)* These amine-reactive, methyl-capped PEO-containing modification reagents are provided as a series of defined chain-length reagents containing 4, 8, and 12 ethylene glycol subunits and an NHS group [57].

*Methyl-$PEG_{12}$–Maleimide* Methyl-$PEO_{12}$–maleimide is a methyl-capped PEO-containing sulfhydryl (SH)-reactive protein modification reagent. This PEGylation reagent has a defined chain length of 12 ethylene glycol/ethylene oxide subunits in the chain, terminating on one

end with a methyl group and on the other end with a maleimide-reactive group [57].

The maleimide group reacts with available –SH groups from naturally occurring or mutagenically derived cysteine residues. Sulfhydryl groups can be incorporated artificially by way of Traut's Reagent (2-imionthiolane), which converts amino groups to sulfhydryl groups. The properties of linear PEGylation reagents are listed in Table 7.

***Sources of PEG*** Union Carbide introduced commercial grades of PEGs to the United States market in 1939. Some of the manufacturers are the Dow Chemical Company, Jefferson Chemical Company, BASF Wyandotte Corporation, Huels, Imperial Chemical Industries, Kuhlmann, Montedison, and Sanyo. Others are NOF, Nektar Inc., Schering-Plough Corp., and Hoffman-La Roche Inc.

Fluka Chemie AG (Germany) is also a source of PEGs of different molecular weights [52]. Polymer Laboratories Ltd. (England) supplies ultrapure PEG or methoxy PEG of low polydispersity to use as standards and small quantities of PEG or functionalized PEG for R&D purposes. Shearwater Polymers Inc. (Huntsville, Al) is a company specialing in PEG that supplies a great variety of products activated toward any amino acid residues as well as heterofunctional PEGs and PEG conjugates [52].

## 4 ACTIVE SITE PROTECTION IN PEGYLATION

Rejection of a substrate from the protein active site attenuates the efficacy of PEGylated molecule. Thus, it becomes important to prevent PEGylation at the active site of the peptide or protein molecule. This can be done by various methods reported by Veronese et al., [52], namely, by using an active site protecting agent during conjugation, which could be an insoluble-resin-linked, pH- or ionic strength-sensitive inhibitor with reversible affinity toward enzymes; a pH-sensitive polypeptide inhibitor or a branched PEG protecting the active site by structural steric hindrance. Modifying the stoichiometric deficiency of PEG by selective isolation of high biologically active PEG isomer or chemical reversible site-directed peptide protection may also solve the purpose.

## 5 IDENTIFICATION OF PEGYLATION SITE

The identification of the PEGylation site in proteins is an essential requirement in order to characterize PEGylated protein and retain their biological activity to the maximum [52].

### 5.1 PEGylation Site Identification in Peptide Conjugates by Edman Degradation

Site identification by Edman degradation is possible only after cleavage of large proteins to smaller peptides [58]. Smaller peptides can be more easily identified than the larger conjugates. However, this method is not very effective for proteins due to prevention of specific cleavage by hindrance of bound polymer chains or difficulty in isolation and purification of smaller chains. However, Monkarsh et al., [59] characterized no-PEGylated interferon-2α by Edman degradation.

**TABLE 7 Properties of Linear PEGylation Reagents**

| Spacer composition | PEO/4 ethylene oxide subunits | PEOS/12 ethylene oxide subunits |

### 5.2 PEGylation Site Identification in Protein Conjugates

A method reported by Sartore et al., [58, 60] using PEGylated lysozyme and PEGylated insulin with methionine in the peptide arm overcomes the difficulty of site identification in larger protein conjugation. In this method, methionine (Met-X) is present in the peptide arm with PEG for protein modification where X is an unnatural amino acid, norleucine (Nle), or β-alanine (β-Ala). Its presence is useful to remove bulky PEG polymer chains from the protein on treatment with cyanogens bromide (BrCN). These de-PEGylated proteins may undergo any chemical or enzymatic cleavage at this point for sequence evaluation. They are also separated easily into positional isomers due to lower hindrance by PEG chains. The cleaved and short peptides are easily identified on the based on linked unnatural amino acids, Nle, and β-Ala as reporter groups which can be detected by amino acid analysis after acid hydrolysis, electrospray mass spectrometry, MALDI-TOF (matrix-assisted laser desorption ionization – time of flight) mass spectrometry or Edman degradation.

### 5.3 One-Step Method for PEGylation Site Identification in Protein Conjugates

A one-step process for identification of PEGylation sites in lysozyme by using a heterobifunctional PEG derivative, biotin–PEG–NHS, was reported by Lee et al., [61]. Lysozyme (MW of 14.3 kDa) and biotin–PEG–$CO_2$–NHS (MW of 3400 Da) were reacted in the presence of 0.1 *M* Tris HCl, pH 8.0, to obtain final lysozyme-to-PEG molar ratio of 5.9:1. PEGylated lysozyme conjugate so formed had a biotin molecule at each PEG chain end and was digested by trypsin to obtain biotin–PEG-conjugated peptide fragments. These fragments were purified and separated by avidin affinity chromatography and reverse-phase high-performance liquid chromatography (RP-HPLC). The eluted fractions of the peptide were analyzed for mass and identification of PEGylation sites by MALDI-TOF mass spectrometry. Extent of PEGylation at each site was determined by RP-HPLC. This method may be applied to other therapeutic proteins also, but without closely located PEGylation site as they might remain unidentified. Furthermore, only biotinylated PEG derivatives can be used for identification of PEGylation sites. The method is time saving and devoid of any tedious procedures.

### 5.4 PEGylation Site Identification Method by Peptide Mapping

Peptide mapping is a method based on digestion of large conjugates with enzymes to smaller peptides and their analysis using RP-HPLC, based on their relative hydrophobicities. The chromatogram patterns of digested PEGylated and mature proteins are then compared to identify the PEGylated site. Capillary electrophoresis can also be used as a complementary separation technique to determine the site of PEGylation and its relative reactivity. Sodium dodecyl sulfate–capillary gel electrophoresis (SDS–CGE) method using a hydrophilic replaceable polymer network matrix can separate linear 12-kDa PEG-conjugated interferons (IFNs) with high resolution [62].

### 5.5 PEGylation Site Identification Method by Tag Labeling

Tag labeling method for protein identification involves a hydrolyzable succinic ester linker that cleaves the protein molecule and PEG chain ends. The labeled succinic acid group in protein can be determined by MALDI-TOF mass spectrometry. Kopecky et al., [63] carried out a study to identify suitable sites on peptide 238/S1 for chemical reaction or modification without affecting its bioactivity. Peptide 238/S1 contains the sequence NH (2)-PYWKWQYKYD-COOH and is capable of blocking any inhibitory antibodies produced against blood clotting factor VIII (FVIII). The highly reactive peptide was identified by mutational analysis. Coupling PEG with N terminus of peptide led to loss of its neutralization property, thus identifying its importance as a site for bioactivity or chemical reaction.

## 6 SITE-SPECIFIC PEGYLATION

During protein modification, a reactive functional group is introduced to link the polymer to the ε-amino group of lysine residues. The process generally aims to prepare an activated PEG with a reactive functional group, which can be conjugated, to the lysine groups on the protein. The number and location of lysine groups vary greatly in native protein, which leads to difficulties in conjugation chemistry of proteins. The stoichiometry of the conjugates and the attachment sites of the polymer occur randomly, which might lead to unexpected reactions in proteins and compromise with protein stability and function. Various approaches to conjugate the polymer with protein at a specific site have been reported, which prevent multiple PEGylation and

maintain the biological activity of the proteins. Each method has its own advantages and disadvantages, and each of them attempt to overcome the deficiencies of the other, which has resulted in an array of different methods for site-specific PEGylation of peptides and proteins.

Gaertner et al., [64, 65] presented a method in which a reactive carbonyl group was formed, instead of a terminal amine group. In case a protein has N-terminal serine or threonine, very mild periodate oxidation is required, which generates a glyoxylyl group. But, another method which is less restricted by the nature of N-terminal residue and requires harsh metal-catalyzed transamination, generates a keto group. At the N terminal of the polypeptide, the aminoxy-functionalized PEG reacts specifically with the generated aldehyde group to form a stable oxime bond. This property has been used for site-specific labeling of interleukin-8 (IL-8). In another study, Gaertner et al., [66] applied this approach to form site-specific attachment of several functionalized polymers varying in size and shape by an oxime linkage to three proteins: IL-8, G-CSF, and IL-1ra. In all cases the reactive carbonyl group reacts with the aminoxy group of functionalized PEG. Various conjugates of the proteins, with different size and shape of linear or branched PEG polymer, were characterized for bioactivity and pharmacokinetic behavior in rats. This approach protected the bioactivity of the proteins as only a single chain of PEG is placed at a specific site on the protein.

However, studies carried out by Balan et al., [67] on site-specific PEGylation using two disulfide bonds and a three-carbon bridge of proteins revealed an interesting fact that when a three-carbon bridge was used to attach PEG, biological activity of the PEGylated protein was found to be independent of the length of the PEG. It was, therefore, suggested that peptides, proteins, enzymes, and antibody fragments can be site specifically PEGylated across a native disulfide bond using three-carbon bridges without destroying their tertiary structure or affecting their biological activity. The stoichiometric efficiency of this approach also enabled recycling of an unreacted protein.

Youn et al., [68] developed and optimized a one-pot, two-step site-specific PEGylation method. This method employs water-soluble organic phosphine where a polypeptide disulfide bridge is first reduced followed by subsequent reaction of two thiols *in situ*. A sCT derivative FMOC-sCT (9-fluorenylmethoxycarbonyl salmon calcitonin) was used for this study, which was FMOC protected at $Cys^{1}$- and $Lys^{11}$-amines among three PEGylation sites including $Lys^{18}$-amine. Site-specific and optimized reactions resulted in the high production yield (86% approx.) of mono-PEGylated salmon calcitonin ($Lys^{18}$-PEG-sCT), compared with that from conventional non-specific PEGylation (18% approx.). The prepared $Lys^{18}$-PEG-sCT conjugate showed improved biological stability and required biological activity. Examples of a few PEG reagents used for site-specific PEGylation are [21] PEG-vinyl sulfone (via free cysteine), PEG–iodoacetamide (via free cysteine), PEG–maleimide (via free cysteine), PEG–orthopyridyl disulfide (via free cysteine), PEG–Hydrazide (via oligosaccharide), and PEG–isocyanate (via alcohol or amino group).

### 6.1 Thiol Selective PEGylation

Thiol being one of the most useful functional groups in bioconjugate chemistry, thiol-selective PEGylation of an introduced cysteine residue by using site-directed mutagenesis, and either maleimide-based or haloacetic-based PEG derivatives, is considered as the most popular method among different site-specific PEGylation methods [14, 69]. The specificity for a suitable site on the protein molecule and the rate of reaction are comparatively better than other protein modifications. However, its use is restricted due to certain limitations [70].

These limitations include the following:

1. As compared to the native protein, the modified or unmodified form of a genetically engineered mutant may have a different structure and function.
2. The yield of properly folded form would reduce if a cysteine mutant forms disulfide isomers with cysteine residues.
3. Although, *N*-maleimide derivative is sulfhydryl group specific, it may react at a very slow rate with amino and imidazoyl groups at pH 7–8.

Zalipsky et al. [71] were the first to report a detailed method to prepare a hetero functional PEG with a thiol group on one terminus (PEG–SH), yielding 80–95% transformation of the functional groups. The synthesis involved glycine amination of [ethoxy-(thiocarbony1)-thiol]-PEG to yield PEG-SH (Fig. 9) [72]. Continuous oxygen removal and anaerobic condition maintenance ensured maximum yield of the thiol group. However, the reaction formed disulfide, which was sometimes the only product formed. Roberts et al., [14] and Veronese [52] have also suggested different thiol-reactive PEGs and reactions to form mPEG–thiol conjugates, which are shown in Figure 10.

### 6.2 PEGylation by Transglutaminase

To overcome the limitations of the earlier site-specific protein PEGylation methods, Sato [69] developed a

**Figure 9** Thiol group introduction on PEG [72].

**Figure 10** Thiol reactive PEGs: (A) PEG orthopyridyl disulfide, (B1) PEG maleimide, (B2) PEG vinyl sulfone, and (C) PEG iodoacetamide [14].

**Figure 11** Schematic representation of site-specific PEGylation of proteins by using (A) M-TGase and (B) G-TGase [69].

novel method using transglutaminase (TGase). According to this method, alkylamine derivatives of PEG are site specifically incorporated into chimeric and intact proteins with higher structural and biological efficiencies. It is comparatively more useful than thiol-selective and the amino-terminus-selective PEG incorporations as the incorporation site of the TGase-catalyzed modification is limited to the substrate Gln residues, the reaction conditions are mild, and dual and site-specific incorporation is possible by utilizing a special substrate sequence (TG2 or FibN) as the appending tag. Figure 11 shows the schematic representation of the site-specific PEGylation of proteins by the use of M-TGase and G-TGase. The authors have elaborately reviewed site-specific PEGylation of proteins in two sections—(i) by using microbial transglutaminase (M-TGase) and (ii) by using guinea pig liver transglutaminase.

## 7 CHEMISTRY OF PEGYLATION

The PEG polymer is required to be activated at one or both of its terminals before it is attached to a molecule [53]. PEG is functionalized by attachment of reactive moieties at both ends. In case the reactive moieties are similar at both terminals, the PEG derivative is termed as "homobifunctional" and if different from each other then it is known as "heterobifunctional" [48]. Reactive amino acids, which can be used as suitable functional groups, are lysine, cysteine, histidine, arginine, aspartic acid, glutamic acid, serine, threonine, and tyrosine [14]. The N-terminal amino group and the C-terminal carboxylic acid can also be used. Lysine and N-terminal amino groups are the most common reactive groups. The presence of lysine leads to replacement of many amines and many lysine modifications, due to which number of PEG molecules conjugate with a single protein molecule, which are also known as "PEGmers" [53]. The number of attachments depends upon the number of ε- and α-amino groups in the proteins. As there is increase in the degree of modification, number of positional isomers ($P$) formed is also increased. This can be calculated by the following equation:

$$P = \frac{N!}{(N-k)! \times k!}$$

where $N$ is the number of possible sites and $k$ is the number of sites modified. Higher degree of modification increases the circulation half-life and decreases the possibility of antigenicity [73]. This type of PEGylation is non-site-specific in nature, whereas site-specific PEGylation could provide better, specific, and reproducible advantages.

A site-directed method of joining proteins to PEG was presented by Bentley et al., [74], which allowed for the preparation of essentially homogeneous PEG–protein derivatives with a single PEG chain conjugated to the amine terminus of the protein. This selectivity is achieved by conducting the reductive alkylation of proteins with PEG–aldehydes at lower pH. Various PEGylation reaction chemistries involve the use of electrophilic activated PEG and ε-amino group of lysine or N-terminal amino group of protein. Some of the examples are, *N*-hydroxysuccinimide-activated esters (amide

bond), PEG–epoxide (alkyl bond), PEG–carbonyl imidazole (urethane bond), PEG–nitrophenyl carbonates (urethane bond), PEG–tresylate (alkyl bond), and PEG–aldehyde (N-terminus, Schiff's base) [21].

### 7.1 First Generation

To maximize the pharmacological benefits of PEGylation, a stable bond is formed between the PEG polymer and polypeptide drug of choice [48]. Chemical activation of the PEG polymer to react with a polypeptide drugs and to maximize the pharmacological efficacy is an advantage [75]. As described previously, ε- and α-amino groups of lysine is most common in proteins and, thus, is utilized mostly for first-generation protein PEGylation. The first-generation PEGylation techniques generally use linear PEGs with lower molecular masses (<12 kDa) forming multiple PEG isomers [76]. PEG used for PEGylation was methoxy-PEG (mPEG), with high PEG diol impurity leading to protein cross-linking and formation of inactive aggregates [77]. These were the key reasons for PEG–drug conjugate degradation, antigenicity, and ultimately stability and clinical problems. First-generation PEG polymers contained groups that were reactive with groups such as anhydrides, acid chlorides, chloroformates, and carbonates [78]. First-generation PEG derivatives that are involved in protein PEGylation are of two types:

1. Alkylating reagents, for example, PEG dichlorotriazine, PEG tresylate, $mPEG_2$-chlorotriazine
2. Acylating reagents, for example, PEG succinimyl carbonate, PEG *p*-nitrophenyl carbonate, PEG trichlorophenyl carbonate, PEG carbonyl imidazole, and PEG succinimidyl carbonate

Examples of first-generation PEGylated proteins approved by the FDA are PEGademase (Adagen), PEGaspargase (Oncaspar), and PEGintron.

### 7.2 Second Generation

The chemistry of second-generation PEGylation is focused on overcoming the limitations or drawbacks of first-generation PEGylation chemistry, namely, diol contamination, restriction to low MW mPEG, unstable linkages, side reactions, and lack of selectivity [48]. Gary Walsh [79] has described various therapeutically applied second-generation biopharmaceuticals. Roberts et al., [14] have discussed second-generation PEGylation by classifying them into different chemistries on the basis of protein modifications:

1. PEG chemistry for amine conjugation
2. PEG chemistry for cysteine modification
3. PEG chemistry for oxidized carbohydrates or N terminus
4. PEG chemistry for reversible PEGylation
5. Heterobifunctional PEG chemistry

***PEG Chemistry for Amine Conjugation*** Primary amine conjugation with aldehydes proceeds through Schiff's base, which reduces to give stable secondary amine linkage (Fig. 12) [14]. A noted example of second generation is mPEG-propionaldehyde, substituted to PEG-acetaldehyde, which is prone to dimerization by aldol condensation [48, 80]. Under acidic conditions (approx. pH 5), the aldehyde of mPEG–propionaldehyde is highly selective for N terminal α amine, which has lower $pK_a$ compared to other nucleophiles. Longer storage stability and higher purity could be obtained by using acetal derivative of propionaldehyde or aldehyde instead of their free forms [81, 82].

Acylating reagents used frequently for protein modification are active esters of PEG carboxylic acid. Ion exchange chromatography is used to purify PEG, achieving high (approx. 97%) purity levels. Other carboxylic acid derivatives developed subsequently over the years, with longer half-lives and lesser reactivity are propionic acid (PEG–O–CHCH–COOH) and butanoic acid (PEG–O–CHCHCH–COOH) derivatives of PEG, their succinimidyl esters (propionic acid-PEG, SPA–PEG, and butanoic acid-PEG, SBA–PEG) and α-methyl branched (PEG–NHS) derivatives [83].

***PEG Chemistry for Cysteine Modification*** Cysteine residue PEGylation is a common strategy for site-specific modification of proteins [52]. The number of free cysteines present on the protein surface is lesser than lysine residues or may be absent too; and in case they are absent, free cysteines can be added on the protein surface by genetic engineering techniques [84]. Such addition may, improve biological activity but may

**Figure 12** Reductive amination using PEG propionaldehyde [14].

also form incorrect disulfide or cause protein dimerization. Some PEG derivatives suitable for PEGylation of cysteine residues are PEG–maleimide (PEG–MAL), PEG–vinylsulfone (PEG–VS), PEG–iodoacetamide (PEG–IA), and PEG–orthopyridyl disulfide (PEG–OPSS) [14]. Generally, these PEGs are thiol reactive and form stable thioether linkage with the protein. However, their stability is pH dependent, different at different (acidic or basic) conditions. Roberts et al., have developed a highly active, long circulating, and stable conjugate of IFN-b using a two-step method with PEG–OPSS [85]. In order to stabilize disulfide linkage in plasma protein between PEG and protein, a low-MW di-OPSS PEG (MW 2000) was coupled to interferon, and the remaining terminal OPSS group was then coupled to PEG thiol [86].

***PEG Chemistry for Oxidized Carbohydrate or N Terminus*** Site-directed PEGylation of proteins can also be carried out by oxidation (enzymatic, e.g., glucose oxidase; or chemical, e.g., sodium periodate) of carbohydrates and N-terminal serine or threonine [87]. Oxidation of carbohydrate residues forms multiple reactive aldehydes which react with either PEG-hydrazide to form hydrazone linkage or PEG-amine to form a reversible Schiff's base. Oxidation of N-terminal serine or threonine in the presence of sodium periodate forms a glyoxylyl derivative that can be further coupled with aminooxy and hydrazide PEG derivatives [88].

***PEG Chemistry for Reversible PEGylation*** PEGylation of peptide and protein drugs can improve their short in vivo circulatory half-life. However, the conjugation between the molecules may not be permanent, which would adversely affect the stability of the PEGylated protein. Development of several PEGylated protein conjugates with stable linkages has various advantages such as easier purification, improvement of circulatory half-life, longer shelf life, and reduction of protein activity possibly due to the presence of the PEG chain at the active or binding site of the protein or steric hinderance at the active or binding site [21]. Development of several protein conjugates with stable linkages can gain such properties.

However, PEGylation often leads to reduction or complete loss of biological and pharmacological activity of the protein. The PEG chain may also restrict the penetration of the bulky molecule only to selective body tissues because of the steric hindrance. These deficiencies of PEGylated peptides and proteins can be overcome by designing a $PEG_{40}$–protein conjugate with a hydrolyzable or enzymatically (serum proteases, esterases) cleavable functional group attached to the PEG chain [21]. Such a type of $PEG_{40}$–protein conjugate is capable of producing native protein at slow and constant rate under physiological conditions with desirable pharmacokinetic parameters. This property, called "reversible PEGylation," was investigated by Peleg-Shulman et al., [89] to improve the short circulatory half-life of the protein by coupling $PEG_{40}$–FMS (2 sulf-9-fluorenylmethoxy-carbonyl) to interferon-α2 (IFN-α2) as $PEG_{40}$–IFN-α2 is inactive in nature. The conjugate was activated by constant regeneration of the native protein by controlled hydrolysis of the FMS. Serum pH and nucleophilicity determine the rate of hydrolysis. Although reversible PEGylation overcomes the problems of conventional PEGylation, the concept itself presents various drawbacks. As for in vivo advantages, this method may not provide any improvement for in situ applications because the cleaving enzymes, such as proteases or esterases, may not be available at a rate-determining step, unpredictability, impracticable utilization, and nonspecific PEGylation leading to complex mixture formation and immunogenic reactions [90, 91].

Shechter et al., presented a new approach of reversible PEGylation. The authors studied the antidiabetic peptide exendin-4, insulin, and human growth hormone (hGH) as model drugs [92]. "Exendin-4 is an insulinotropic glucagon like peptide-1 agonist that associates with β-pancreatic cells, elevates endogenous cAMP levels, enhance secretion of Insulin, and lowers circulating glucose levels" [92, 93]. The basic hypothesis was to entrap a pharmacologically silent conjugate in the circulatory system releasing the parent peptide/protein through a nonenzymatic hydrolyzing pathway, which was exclusively dependent on pH, temperature, and protein content, and preserved in mammalian tissue fluids under strict homeostasis [89]. Several $PEG_{40}$–FMS–peptide/protein conjugates were prepared, and their efficacy in facilitating prolonged effects in mice, following a single subcutaneous administration, was studied. All conjugates were highly soluble in aqueous neutral media as inclusion of highly hydrophilic $PEG_{40}$-chain within the conjugate compensated the lowered solubility gained by the covalently linked FMOC (9-fluorenylmethoxycarbonyl) moieties (Fig. 13). The prodrug character of prepared conjugates allowed the administration of higher doses with no risk of toxicity, downregulation, or desensitization. Slow release of the covalently linked polypeptide drug maintained prolonged action over many hours. Thus, reversible PEGylation reduced the tendency of conventional PEGylation to inactivate short-lived therapeutic peptide and protein and extended their half-life, bioavailability, and efficacy. In another study, Shechter et al. [94] developed a reversibly PEGylated $PYY_{3\text{-}36}$ (peptide $YY_{3\text{-}36}$) derivative by coupling it to a 40-kDa PEG through a spontaneously cleavable linker. The resulting conjugate ($PEG_{40}$–FMS–$PYY_{3\text{-}36}$), a 1:1 conjugate of $PEG_{40}$–FMS

**Figure 13** Preparation of monomodified PEG40–FMS–peptide [89, 94].

covalently attached to $PYY_{3\text{-}36}$, gradually released unmodified $PYY_{1\text{-}36}$ in vivo, exhibiting an eightfold increase in its functional half-life, to approximately 24 h.

Tsunoda et al. developed another novel method for polymer-conjugated cytokines using TNF-α (tumour necrosis factor-α) as a model, with higher efficiencies, and investigated the usefulness of the resultant conjugate in vivo [94]. TNF-α and PEG were used for polymer conjugation, by using a pH-reversible, amino-protective reagent, dimethylmaleic manhydride (DMMAn). Significant improvements in antitumor activity were observed in vivo as compared to the changes in specific activity. Native TNF caused dose-dependen body weight loss in mice, whereas no obvious side effects were observed in any mice treated with PEG–TNF-α. PEG–TNF-α(+) had 20–30% higher specific activity than PEG–TNF-α(−), which was not treated with DMMAn.

***Heterobifunctional PEG Chemistry*** Hydrophilic, flexible, and biocompatible PEG derivatives with different terminal reactive groups used as spacers to link two macromolecular moieties, targeting of drugs, liposomes, or viruses to specific tissues are known as heterobifunctional PEGs [14]. Bentley et al. [95] prepared heterobifunctional PEGs by first initiating PEG polymerization with benzyl alcohol to produce benzyl PEG (Bz–PEG–OH). The hydroxyl group of the intermediate polymer is converted to a first reactive functional group. The benzyl group can then be removed by a hydrogenolysis functional group, thus making available a new terminal hydroxyl group for the addition of a second functional group. A promising strategy for generating heterobifunctional PEGs is the polymerization approach. Initiating polymerization of ethylene oxide with an anion that ultimately becomes the end group of PEG is the most direct route for heterobifunctional synthesis. Terminating the reaction with water generates a hydroxyl group at the second terminal end that can undergo activation by chemical methods. For example, this method has been used by Yokoyama et al., [96] to prepare a PEG with a hydroxyl group at one terminus and an amino group at the other. This strategy has its limitations. Only those anions that are desirable as end groups and suitable for initiating polymerization are useful for synthesis of heterobifunctional PEG by this route. This method is also limited by the fact that rigorous exclusion of water is necessary to prevent the formation of diol. This problem becomes more severe as PEG molecular weight increases. If these drawbacks are resolved, generating heterobifunctional PEG reagents by anionic polymerization may be the most efficient and cost-effective method. These PEG derivatives are also useful in immunassays, biosensors, probes, and bioconjugation techniques. Several heterobifunctional PEG derivatives can be prepared by methods such as anionic polymerization of ethylene oxide onto an initiator containing a protected functional group and terminated by alkylation, for example, α-amino-ω-hydroxy–PEG

**Figure 14** PEG-based heterobifunctional *N*-succinimidyl-3-(2 pyridyldithio) propionate (SPDP) analog [72].

**Figure 15** PEG reagents for arginine modification [72].

$[NH_2(O–CH_2–CH_2)_nOH]$ for bioconjugation applications [71]. Zalipsky et al. reported a method to prepare pure heterobifunctional PEGs with two different functional groups at their end terminals, containing an amino or carboxyl groups at one of the termini [82].

Allen et al., [72, 98] used a macromolecular analog of SPDP [*N*-succinimidyl-3-(2 pyridyldithio) propionate], a PEG-based heterobifunctional reagent (Fig. 14) to prepare long circulating immunoliposomes. This reagent is used to link ligands to biomaterials and for protein–protein cross-linking.

Oligomeric heterobifunctional derivatives containing maleimide, iodoacetate, dithiopyridyl, and succinimidyl ester groups were prepared and used for preparation of protein conjugates interlinked through flexible and well water solvated oligo ethylene oxide spacers.

### 7.3 Carboxyl Group Modification

Carboxyl groups can be introduced onto PEG by various methods. Carboxymethylation of PEG with a haloacetic acid or its esters is a simple method for quantitative carboxylation of the polymer's end groups. Displacement of the bromide in ethyl bromoacetate with PEG–alkoxide, followed by saponification of the ester can also be carried out easily [72, 99].

Strong oxidizing agents, for example, permanganate [100], can cause polyether chain degradation and should be causiously used with PEG. Carboxylic acid groups at PEG terminals can also be substituted by modification with succinic (or glutaric) anhydride. Various organic solvents and specific pH conditions are utilized at different steps of synthesis. Formation of the final product depends upon the presence and type of catalyst used in the reaction, that is, the presence of only dicyclohexylcarbodiimide (DCC) as a catalyst does not lead to the formation of any ester or amide but forms *N*-acylurea derivative. However, DCC when used along with *N*-hydroxybenzotriazole (HoSu) forms amides and esters of various primary amines and alcohols [101]. Succinimidyl esters of carboxymethylated and succinylated PEGs are the most widely used reagents for modification of proteins, lipids, and other substrates [102, 103].

Kynclova et al., [104] reported a new method for covalent attachment of PEG to carboxylic groups of proteins (lipase from *Candida rugosa*) using *O*,*O*-bis-(2-aminopropyl)–PEG and carbodiimide/*N*-hydroxysuccinimide. Mild acidic pH conditions were favorable for higher protein activity, identification of preferred site, and most dominant isomer.

### 7.4 Arginine Modification

PEG reagent for selective modification of arginine residues [72] (Fig. 15A) was prepared by coupling camphorquinone 10-sulfonylchloride to amino-PEG [105]. The synthesized PEG reagent forms PEG–peptide conjugates in borate at pH 9, at 37°C. Such linkage between the components of the conjugates was cleavable by a treatment with *o*-phenylenediamine and was also stable to a variety of acidic and nucleophilic reagents. Thus, arginine modification was found to be suitable for enzymatic and chemical alterations of peptides, taking advantage of the properties of PEG for convenient purification of the final modified peptide and intermediate products. Another PEG reagent applied for selective modification of arginine residues of polypeptides is phenylglyoxal [106]. Attachment of its mPEG analog (Fig. 15B) to various proteins was carried out at room temperature and pH range of 5.5–9.3. It was characterized by a decrease in arginine content as determined by amino acid analysis of the conjugates.

### 7.5 OH Group Conjugation

The terminal primary hydroxy group of PEG is the most common site for drug–PEG conjugation reactions [107]. All the conjugates prepared from PEG–OH and free carboxylic acids under relatively mild conditions are summarized in Table 8. One of the most common approaches, that is, the conjugation of dicyclohexylcarbodiimide in the presence of methylaminopyridine as the carboxylic acid transformation into PEG esters occurs at room temperature, utilizing less time (2–4 h) with better results [108, 109]. In aqueous conditions, such esters may undergo hydrolysis, thus dissociating the conjugate components. The rates of hydrolysis depend on the nature of the carboxylic acid, molecular

**TABLE 8 Application of PEG–OH and Carboxylic Acid Conjugation**

| Sl No. | Drug | MW of PEG | Reagent/Condition[a] | Comments |
|---|---|---|---|---|
| 1. | Ibuprofen | 200, 900, 2000 | CDI in $CHCl_3$ at 60°C | Longer-lasting anti-inflammatory activity of PEG derivatives was observed. |
| 2. | Ursodeoxycholic acid | 1000, 2000 | CDI in $CHCl_3$ at 60°C | An efficient method for PEG esterification applicable to bile acids was demonstrated. |
| 3. | 2-Bezoxazolon-3-yl acetic acid | 200–1000 | DCC in THF | Conjugate of PEG-400 was used as a substrate in penicillin amidase-mediated synthesis of new biologically active cephem. |
| 4. | Benzoylacrylic acids | mPEGs 550–1900 | DCC/pyridine in $CH_2Cl_2$ | Antimicrobial activities were studied in vitro. |
| 5. | Penicillin V | mPEG-2000, 3000, 4000; poly(PEG-Lys) 50,000 | DCC/DMAP | Efficient esterification demonstrated. The conjugate is readily hydrolyzed releasing an active antibiotic. |
| 6. | Aspirin | 400, 1000, 3000 | DCC/DMAP | Aspirin esterification used as a model reaction for efficient synthesis of PEG–ester conjugates. |

[a]CDI: *N*,*N*´-carbonyl diimidazole; DCC: *N*,*N*´-dicyclohexylcarbodiimide; DMAP: 4-dimethylaminopyridine; THF: tetrahydrofuran.

weight of PEG, pH, and temperature. Predicted half-life times of this ester hydrolysis can range between several hours at pH 7.4 in phosphate buffer. Accordingly, it could be applied as an approach for slow release of an active drug under physiological conditions. However, use of appropriate spacers, such as succinate, can allow the use of PEG esters of a larger selection of drugs. Atropine and quinidine were successfully linked via ester linkages to PEG-succinates of various molecular weights [108].

Direct attachment of drugs to hydroxyl groups of the polymer is also possible by forming ether, carbonate, and urethane bonds via the appropriate alkylation and acylation reactions. For example, Khue and Galin [110] prepared carbonate-linked conjugates of hydrocortisone and dexamethasone by reacting their chloroformate derivatives with HO–PEG, where the derivatives were selectively formed on the primary hydroxyl groups. The yields of the coupling reactions were low to moderate. Anti-inflammatory steroids from the conjugates due to hydrolysis of the carbonate linkage was pH, temperature, and steric hindrance dependent [111]. Hydrolytic rates of PEG-steroid carbonates indicated the reaction to be base catalyzed. In a few cases, attachment of biologically relevant molecules to PEG was achieved directly by utilizing the reactivity of terminal primary OH groups of the commercially available polymer. In most cases, however, suitable functionalization of the polymer was observed to be an essential first step during formation of final conjugate. In the biological literature this process is often referred to as "activation" of the polymer [107].

Two principal approaches used to prepare functional derivatives of PEGs are [72] (1) direct transformation of hydroxyls to the new target functionality and (2) reaction of the polymer with a bifunctional molecule so that one function forms an attachment to the polymer and the other one remains available for further chemical transformations. Both approaches are often used, and each has its merits, which should be considered when planning a specific conjugation strategy. Table 9 shows various PEG conjugates and their applications.

Reaction of primary hydroxyl groups of PEG with organic sulfonyl chlorides was used extensively as a method for placement of good leaving-group residues at the polymer terminals and as an alternative to halogenation of PEG–OH [72]. Sulfonate esters display higher reactivity than halides and are often used as convenient starting materials for preparation of functionalized PEGs namely amino, thiol [71], and phenylglyoxal [112] to name a few. Tosylate-PEG is the most commonly used sulfonate ester. Several variations on the synthesis of this derivative claimed to provide complete transformation of the functional groups [56, 60].

## 8 LYOPHILIZATION OF PEGYLATED PROTEINS

Freeze-drying is the separation of liquid water from a solution frozen to ice by vacuum sublimation, leaving the solutes in an anhydrous or almost anhydrous state [113]. Lyophilization maintains bioactivity and stability of protein formulations over their shelf life. Stability of protein formulations can be improved by the addition of a lyoprotectant or cryoprotectant such as a carbohydrate, for example, sucrose and trehalose, during the lyophilization process [114]. These cryoprotectants form

**TABLE 9 Various PEG Conjugates and Their Applications**

| Sl. No. | PEG Conjugates of | Useful Properties and Applications |
|---|---|---|
| 1. | Drugs | Improved solubility, controlled permeability through biological barriers, longevity in bloodstream, controlled release |
| 2. | Affinity ligands | Used in aqueous two-phase partitioning systems for purification and analysis of biological macromolecules, cells |
| 3. | Cofactors | Bioreactors with continuous regeneration and recycling of macromolecular cofactors |
| 4. | Peptides | Improved solubility, conformational analysis |
| 5. | Proteins | Resistance to proteolysis, reduced immunogenicity and antigenicity, longevity in bloodstream. Uses: therapeutics, organic-soluble reagents, bioreactors |
| 6. | Saccharides | New biomaterials, drug carriers |
| 7. | Oligonucleotides and analogs | Improved solubility, resistance to nucleases, cell membrane permeability |
| 8. | Lipids | Used for preparation of PEG-grafted liposomes |
| 9. | Liposomes and particulates | Longevity in bloodstream, RES evasion |
| 10. | Biomaterials | Reduced thrombogenicity, reduced protein and cell adherence |

an amorphous or partially amorphous stabilizing matrix in the protein formulation, which in turn restrict mobility and reactivity, reduce aggregation [115], and enhance molecular interactions by hydrogen bonding between carbohydrates and proteins [116].

Mosharraf et al. [117] carried out a detailed study on lyophilization of PEGylated growth hormone antagonist (PEGvisomant) as a model protein. They determined the effect of formulation and process parameters on the solid-state properties such as degree of solid-state disorder (amorphicity), protein–PEG–excipient interactions, moisture-induced recrystallization of amorphous samples, cooling rates for the solid-state properties, and dissolution characteristics of the resultant lyophilized cakes. Interactions between sucrose and PEGylated protein molecules were demonstrated by cooling rates, decrease in $T_m$, and melting enthalpy of PEG, which were determined by differential scanning calorimetry (DSC) and isothermal microcalorimetry (IMC). Moisture-induced recrystallization of the lyophilized cakes was not prevented by PEGylation. Ratio of protein to lyoprotectant or stabilizer also affected the stability of the lyophilized formulation. In a study carried out by Tattini et al. [118] different ratios (1:0.25 and 1:0.50) of bovine serum albumin to polyethylene glycol (BSA:PEG) were used. BSA–PEG in a ratio of 1:0.25 was found to have better structural stability and optimized conditions for lyophilization and protein storage as compared to that of 1:0.50. Another protein stabilizer or lyoprotectant reported to prevent protein aggregation caused during lyophilization is inulin. It has been used to stabilize PEGylated nanoparticles and liposomes. Inulins and dextrans can prevent protein aggregation of plasmid DNA and PEGylated or non-PEGylated polyethylenimine (PEI) complexes [119]. However, inulins are found to be more effective over dextrans for PEGylated proteins or protein formulations due to their compatibility with PEG. Freeze-drying and freeze-thawing of 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP)/dioleoyl-phosphatidyl-ethanolamine (DOPE) liposomes and egg phosphatidyl choline (EPC)/cholesterol (CHOL) liposomes can be stabilized by using inulin [120].

Another mechanism explaining the degradation of proteins during freeze-drying or lyophilisation was reported by Heller et al. [5]. In this study, the effect of PEGylation on the conformational stability and partitioning behavior of therapeutic proteins in two-phase systems (PEG–dextran) during lyophilisation process were determined. PEGylated and non PEGylated forms of hemoglobin and brain-derived neurotrophic factor (BDNF) were partitioned separately in PEG–dextran phase separating systems. Partition coefficients of both PEGylated and non-PEGylated proteins were obtained from the ratio of their concentrations in PEG and dextran phases, respectively. Protein concentration in each phase for BDNF and PEGylated BDNF was measured by ultraviolet (UV) analysis at 280 nm, whereas haemoglobin and PEGylated haemoglobin were analyzed by BCA total protein assay. For primary drying the samples were freeze dried at –20°C for 1000 min at 60 mT vacuum after annealing at –7°C for different time lengths followed by cooling below –30°C for 120 min and for secondary drying, 0, 10, and 25°C for 120 min at 60 mT vacuum. Both the proteins behaved differently in PEG–dextran two phase systems. PEGylated haemoglobin and BDNF were found to have greater affinity toward the PEG-rich phase than the dextran-rich phase. In case of PEGylated BDNF, the affinity for the PEG-rich phase is enhanced, whereas haemoglobin exhibited more affinity toward the dextran-rich phase. These results confirm the alteration in partitioning behavior of

proteins after PEGylation, thus its surface characteristics and interaction with other surfaces, interfaces, and cosolutes [120]. Therefore, depending upon the properties of given therapeutic protein and its compatibility with added excipients, PEGylation can have favorable or unfavorable effect on lyophilization and ultimately on its stability.

## 9 CHARACTERIZATION OF PEGYLATED PRODUCT

### 9.1 Physicochemical Characterization of PEGylated Products

Solid-state properties such as internal cake structure and porosity, residual moisture, weight ratios of protein:PEG:sucrose (w/w/w), PEG melting endotherm, sucrose crystallization exotherm, sucrose melting endotherm, sucrose degree of disorder, PEG degree of disorder (amorphicity) of lyophilized PEGylated protein formulations, determined by Mosharraf et al. [117], have already been introduced briefly in Section 8. Different methods to determine these solid-state properties of "lyophilized" PEGylated proteins are presented next.

***Internal Cake Structure and Porosity*** The study carried out by Mosharraf et al. [117] was the first to report the effect of cooling rate on the pore size of a lyophilized PEGylated protein. Each lyophilized cake was sliced into three pieces. The middle slice was then scanned using a scanning electronic microscope under an acceleration voltage of 20 kV with 75× and 300× magnifications. Scanning electron microscopy photomicrographs revealed that the cakes, which were lyophilized at a cooling rate of 0.11°C/min had a smaller pore size and a more homogeneous pore distribution within the cake structure than in the corresponding formulations cooled 10 times faster at 1.1°C/min. As the size and number of ice nuclei are related to the degree of supercooling, higher degree of supercooling leads to smaller crystals. It was also concluded that increase in sucrose concentration (added to the protein as lyoprotectant) decreased the pore size. Some scientists [5, 121], however, reported that faster cooling rates lead to higher rate of nucleation and hence smaller ice crystals. When colyophilized rhGH analog/sucrose formulations were compared at different amounts of sucrose (5, 25, and 50 mg/mL) at the same cooling rate (0.11 or 1.1°C/min), a decrease in pore size was observed with increasing amounts of sucrose.

***Determination of Residual Moisture*** As stated in Mosharraf and co-workers: "The percentage of residual moisture in each formulation was determined using a 684 Karl Fischer coulometer. A solution of methanol and formamide (70:30) was used as solvent, to extract the moisture from the solid cake. For each formulation, three cartridges were analyzed, and the average percent residual moisture and standard deviation (S.D.) were calculated" [117, p. 220].

Residual moisture contents in lyophilized sucrose formulations were approximately 1.7–3.5%, whereas in all other lyophilized formulations, the water content was <1%, indicating efficient drying. It was observed that cooling rate did not affect the moisture content, but the additio n of PEG in the formulation reduced the moisture content of the lyophilized cake.

It was also observed that PEG and protein influence the amount of residual moisture in formulations containing sucrose. On comparing water content in the PEGylated protein formulations with that in the non-PEGylated protein formulations, it was found that PEGylation caused a decrease in water content. PEGylation may alter the ability of protein to bind to water, thus increasing the tendency of water to leave the lyophile during secondary drying.

***X-Ray Powder Diffraction (XRPD)*** Diffraction patterns of the materials were obtained using a diffractometer, with CuKα radiation at 45 kV and 40 mA [117]. The samples were scanned in steps from 5° to 45° (2θ), the crystalline ordered structure of sucrose. The XRPD pattern for crystalline sucrose showed sharp peaks indicative of long-range order. The patterns for the lyophilized formulation of PEGylated rhGH analog in 50 mg/mL sucrose and quenched sucrose both have broad, diffuse spectra typical of a highly disordered (amorphous) structure.

***Differential Scanning Calorimetry*** As stated in Mosharraf and co-workers: "DSC experiments were performed on a DSC 220. Special attention was paid to minimizing the exposure of the samples to moisture prior to DSC analysis. Rubber-stoppered cartridges containing samples were opened in a nitrogen flushed chamber. Immediately after opening, the freeze-dried cake was gently disintegrated and a sample of approximately 2.5–3.5 mg was accurately weighed in an aluminium pan and sealed hermetically. An empty pan was used as reference. The sample and the reference were exposed to a linear heating ramp in the temperature range 20–225°C at a heating rate of 5°C/min in an atmosphere of (100%) nitrogen. For each formulation, duplicate samples were analyzed ($n = 2$). Exothermic signals were given positive values" [117, p. 221].

From the DSC curve obtained, it was found that at slow cooling rates the degree of solid-state disorder of

sucrose was dependent on sucrose concentration in the pre-lyo solution. Lyophilization of PEGylated protein without excipient at a slow cooling rate resulted in partially crystalline cakes with higher degree of crystallinity, which could be due to the presence of PEG molecules. Thus, it can be concluded that PEG increases the crystalline character of the cakes [122]. The presence of crystalline character in the samples was determined by interpretation of DSC scans, which revealed characteristic crystal melting endotherm [5]. Both IMC and DSC results confirmed the partial crystalline characteristic of the lyophilized pegylated protein. Furthur, it was also observed that PEG–protein conjugation altered the physicochemical properties of PEG as well as protein.

***Isothermal Micro Calorimetry*** As stated by Sebhatu and co-workers: "The IMC experiments were performed in a thermal activity monitor (TAM) using the ampoule method" [123, p. 137]. Three to six freeze-dried cakes were removed from the cartridges, disintegrated, and pooled. A sample of about 100 mg of the disintegrated cake (powder) was placed into a vial, weighed carefully, and analyzed in the microcalorimeter. Samples of crystalline sucrose and quenched sucrose were also tested. Storage of disordered material at high relative humidity leads to water vapor absorption and recrystallization due to which low relative humidity (RH) (57.5%) was maintained during the experiment by placing a glass tube containing saturated NaBr solution into the vials, which were then sealed. An empty glass tube in a sealed vial was used as reference. The sample and reference vials were equilibrated in the TAM for 15 min before starting the experiment. All experiments were performed at 25°C. The heat flow signal ($dQ/dt$ in microwatts) was monitored as a function of time. The heat flow curve obtained for a pure amorphous reference usually consists of a moisture absorption phase and a recrystallization phase. Because of overlapping moisture absorption and recrystallization peaks, the heat of interaction with water ($Q$, measured in joules) was calculated by integrating the total area under the heat flow curve [124]. The values were normalized for eventual weight differences. These values were used to calculate the degree of solid-state disorder.

Lyophilized sucrose and lyophilized PEGylated protein formulation were not analyzed by this method because of sample limitations. The degree of disorder in the remaining formulations was calculated using the $Q$ value of quenched sucrose as the 100% amorphous reference. The 100% amorphicity of this sample was verified by XRPD. The degree of disorder was determined by dividing the $Q$ value obtained for the sample by that of quenched sucrose and multiplying by 100. Except for crystalline sucrose, all the samples interacted with water vapor resulted in exothermic peaks. In all cases except that of crystalline sucrose, the samples interacted with water vapor, resulting in exothermic peaks demonstrating the amorphous character of the lyophilized and quenched samples. The $Q$ values were considered as heat of recrystallization and were calculated by integration of heat flow curves [124] and normalized for the weight of the samples. The degree of disorder in the formulations containing sucrose was calculated using the $Q$ value for quenched sucrose (41.5 ± 9.2 mJ/mg) as the 100% amorphous reference. The crystalline sucrose sample did not react with moisture, confirming a totally crystalline structure for this sample.

***Ion Exchange Chromatography (IEC)*** High-performance ion exchange chromatography (HP-IEC) can be performed on an analytical scale Mono S column, using a Protein Purification System [125]. The column is previously equilibrated with 0.04 *M* sodium acetate, pH 5.0 (buffer A) for 10 column volumes, at a flow rate of 0.2 mL/min at room temperature. Samples are loaded and washed with one column volume of buffer A. Subsequently, the column is eluted with a linear gradient to 100% of the same buffer containing 0.15 *M* sodium chloride (buffer C, pH 5.0) over 15 column volumes, monitoring the absorbance at 280 nm. The HP-IEC results of two monomer conjugates, mono-PEGylated rhIL-1ra with SC-$PEG_{5k}$ and mono-PEGylated rhIL-1ra with SC-$PEG_{10k}$ revealed that rhIL-1ra was composed of 153 amino acids with an MW of 17.5 kDa. It was also observed that the attachment of polymer was prone to occur at imidazole groups of histidine, which was independent on peptides or proteins [126]. The same ionic properties of purified monomeric conjugates on analytical Mono S column and the same hydrophobic behaviors on analytical C4 column suggested that rhIL-1ra might be site-specifically PEGylated.

***Zeta Potential Measurement*** Surface charge of PEG–PIBCA (poly-iso-butyl cyanoacrylate) nanoparticles prepared at different pHs (0.75–1.5) was studied by zeta potential measurement in phosphate-buffered saline (PBS) containing KCl and also repeated with water to evaluate the influence of ionic strength on the zeta potential [127]. Surface hydrophobicity of PEG–PIBCA nanoparticles was investigated by HIC (hydrophobic interaction chromatography). HIC is a technique of column chromatography capable of separating material on the basis of its interaction with a hydrophobic gel matrix [128]. The sample suspension was injected into a column filled with propyl agarose and connected with a pump. Elution was performed using PBS containing NaCl. Washing was carried out with a buffer containing Triton X-100. Optical density of the eluted samples was

determined spectrophotometrically at 400 nm. HIC was performed on PIBCA and PEG-coated PIBCA nanoparticles, prepared at pH 0.75–1.5.

PEG–PIBCA nanoparticles prepared at pH 1–1.5 presented, in PBS, a mean zeta potential of 218 mV, whereas when the pH of the polymerization medium was 0.75, the surface charge was much more negative (230 mV). When suspended in water, nanoparticles prepared at any pH exhibited the same zeta potential (230 mV). Hydrophilic surface properties (determined by HIC) showed that only particles produced at pH 1–1.5 presented a more hydrophilic surface. Nanoparticles prepared at pH 0.75, as well as noncoated PIBCA nanoparticles, interacted with the propyl-agarose and were eluted through the column only after washing with Triton X-100.

Interestingly, data relative to surface charge can be compared to PEG association to nanoparticles as a function of the pH. At pH 0.75 a very negative surface charge corresponded to a very low PEG association, whereas at pH 1 surface charge was less negative and PEG content higher. This suggested at least a partial PEG disposition on the nanoparticle surface, even if the PEG total content was reduced in nanoparticles prepared at pH 1.25 and 1.5 when compared to nanoparticles prepared at pH 1. No differences were observed by varying the pH of the polymerization medium, suggesting a strong influence of the higher ionic strength of the medium (PBS/KCl).

### 9.2 Biochemical and Biological Characterization of PEGylated Proteins

***Protein Determination [21]*** Commonly used methods to determine the concentration of protein in a sample are, for example, bicinchoninic assay (BCA) [129], enzyme linked immunosorbant assay (ELISA) [130, 131], ultraviolet spectroscopy, and Bradford assay. Amino acid composition analysis is also used and considered an accurate method for protein analysis.

According to the Bradford method [132], protein concentrations can be determined spectrophotometrically using Coomassie Brilliant Blue G-250. Crystalline BSA was used to prepare standard curve. Absorbance was read at 595 nm.

***SDS–PAGE (Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis)*** SDS is an anionic detergent that denatures proteins by "wrapping around" the polypeptide backbone, and SDS binds to proteins fairly specifically in a mass ratio of 1.4:1. In doing so, SDS confers a negative charge to the polypeptide in proportion to its length, that is, the denatured polypeptides become "rods" of a negative charge cloud with equal charge or charge densities per unit length. It is usually necessary to reduce disulfide bridges in proteins before they adopt the random-coil configuration necessary for separation by size: This is done with 2-mercaptoethanol or dithiothreitol. At a given pH and under nondenaturing conditions, the electrophoretic separation of proteins is determined by both size and charge of the molecules [133].

All proteins have a large negative charge, which means they will all migrate toward the positive pole when placed in an electric field [134]. In denaturing SDS–PAGE separations, therefore, migration is determined not by intrinsic electrical charge of the polypeptide but by molecular weight gels of given acrylamide concentration that separates proteins effectively within a characteristic range. Very large polypeptides cannot penetrate far into a gel, and thus their corresponding bands may be too compressed for resolution. Polypeptides below a particular size are not restricted at all by the gel, and regardless of mass they all move at the same pace along with the tracking dye. Gel concentration should be selected so that the proteins of interest are resolved.

SDS–PAGE analysis of PEGylated proteins can be performed according to the method described by Laemmli [135]. The gels can be stained specifically for protein or PEG. Staining for PEG is done according to a modified procedure of Kurfurst [136]. SDS–PAGE gels are rinsed with distilled water and placed in a 5% barium chloride solution for 10 min. After rinsing the gel with distilled water to remove barium chloride, the gel is placed in 0.1 *M* Titrisol for another 10 min. After washing away the yellow Titrisol, the gel is stored in distilled water in a heat-sealed bag in the dark.

The polyacrylamide concentration was 5% in the stacking gel and 12% in the separation gel, using a Miniprotein III cell. Each sample was mixed with the fivefold reducing buffer, boiled for 5 min, and loaded into each well. Silver staining was used to visualize the proteins [125].

***Determinaton of Molecular Weight of PEGylated Proteins*** Several methods have been used to determine the molecular weight of PEGylated proteins, namely mass spectroscopy (electrospray ionization mass spectroscopy or MALDI-TOF mass spectroscopy) [137], SDS–PAGE analysis, and CE (capillary electrophoresis) analysis [138], each method having its own advantages and disadvantages.

***Identification of PEGylation Site and Positional Isomers*** The process to identify a suitable PEGylation site and its positional isomers involves various steps (as discussed in Section 5, and thus different analytical

methods may be required at each step. Some common methods used to identify PEGylation sites on protein molecules and their positional isomers are ion exchange chromatography, size exclusion chromatography (SEC) [139], high-performance liquid chromatography (HPLC), reversed-phase HPLC, peptide mapping, Edman degradation, amino acid analysis, MALDI-TOF mass spectroscopy [137], and Raman spectroscopy and nuclear magnetic resonance (NMR) [138].

***Estimation of Grafting Density/Degree of PEGylation/Extent of PEGylation/Modification Extent*** The determination of polymer content in PEGylated proteins, that is, modification extent, is essential in order to control the half-life, maintain manufacturing uniformity, and satisfy regulatory concerns [140]. Various methods have been reported to determine modification extent. Some of the useful methods are discussed next.

*TNBS (Trinitrobenzene Sulfonic Acid) Method [141]* The TNBC method is the most commonly used method to obtain modification extent of PEG compounds due to its speed and simplicity. However, this colorimetric method detects only modified lysine reactivity and not actual numbers of PEG in the protein [142]. According to this method, serial dilutions of the native RP (recombinant protein) and RP–PEG are made in 100 m*M* sodium phosphate (pH 8.3), followed by the addition of the TNBS reagent. The reactions are then heated to 40°C for 2 h. The absorbance is determined and absorbance versus protein concentration graph is plotted from which a slope of the line is calculated. The number of PEG molecules attached to each molecule of RP = 1 − (slope of native RP/slope of RP–PEG) × 29, where 29 represents the number of primary amines present in RP (28 lysines + 1 N terminal).

*Microfluidics Assay* Yu et al. investigated a simple CE-based method to separate PEGylated conjugates and quantitate the separated species [142]. Separation is based on relative molecular size in the presence of SDS. The method is consistent and fast (90 s/sample analysis), and it consumes a limited sample (up to 4 μL). Even more advantageous, this method does not require post-electrophoretic handling such as the staining and destaining of PAGE. Each protein 200 LabChip contains an interconnected set of microchannels in which proteins (mixed with a fluorescent dye and SDS) are sieved by size as they are pulled through a polymer matrix by electrical current. At the end of the channel, separated proteins are mixed with a destaining solution and quantitated with a sensitive fluorescence detector that is connected to a computer for run control and automated data analysis. Each species of PEGylated protein has its size and relative concentration reported. It can provide data output in either an electropherogram or a simulated slab gel picture format, and it is well suited for electronic record storage.

An Agilent Bioanalyzer equipped with Chip Priming Station, Protein 200 plus LabChip kit, and the Agilent software was used for analysis. Typically, concentrated protein RP–PEG samples were diluted to 0.5–1 mg/mL in PBS saline and free RP was diluted to 0.1 mg/mL to acquire peaks distinguishable from the baseline. Standard sample preparation involved mixing 2 μL of 100 μg/mL RP or 1000 μg/mL RP–PEG with 4 μL reduced sample buffer. Samples were then incubated at 95°C for 5 min, and then 84 μL of distilled water was added followed by loading of 6 μL of the mixture onto the Protein 200 Chip (along with other reagents) to the appropriate wells. Two internal markers are mixed with each test sample and with a molecular weight reference "ladder." The quantitation is calculated by comparing corrected peak area with either an upper internal marker or a standard reference.

Other methods that have been used for determination of modification extent are NMR, amino acid analysis, capillary zone electrophoresis (CZE), matrix-assisted laser desorption/ionization–mass spectrometry (MALDI–MS), Fourier-transform infrared spectroscopy (FTIR), Raman spectroscopy, online size-exclusion high-performance liquid chromatography (SE-HPLC), and light scattering differential refractometry methods [137, 139, 143–145]. Although these methods are much more accurate than TNBS and fluorimetric methods, they are less popular as these methods require tedious operations, sophisticated equipments, and skilled operators. Secondly, these methods consume PEGylated proteins, which are generally costly. Thus, Gong et al. [140] have reported another alternative method, which is comparatively simpler and cost effective. The free PEG in the given sample was determined according to the procedure of Sims and Snape [146] with some modifications.

Briefly, samples were diluted with distilled water to final concentrations of PEG within the range of 0–7.5 μg/mL. To an 800-μL sample, 200 μL barium chloride solution and 100 μL iodine solution were added subsequently. The reagent blank was prepared as above with distilled water instead of sample. Solutions were agitated to ensure adequate mixing. Color was allowed to develop for 15 min at room temperature, and then absorbance was read at 535 nm. Inactivated PEG, which has the same molecular weight as that of free PEG, was used to prepare a standard curve. The concentration of free PEG was estimated from the standard curve. Modification extent was calculated according to

$$\mathrm{ME} = \left(\frac{m_a - m_c}{m_b \times N_b}\right) \times 100 \quad (1)$$

where ME is the modification extent, $m_a$ the molar amount of PEG used for modification, $m_b$ the molar amount of protein, $m_c$ the molar amount of free PEG, and $N_b$ is the amount of target group in a one-protein molecule.

***In Vitro Release Studies of PEGylated Products*** Dissolution studies of lyophilized PEGylated proteins can be carried out by a method described by Mosharraf et al. [117]. According to this method, the rear compartment of a dual-chamber cartridges was filled with 1 mL water for injection (WFI) and sealed. The cakes were then reconstituted using a threaded mixing device. The cartridges were turned over every 30 s manually until a clear solution was obtained. The time taken for dissolution of the cake was measured. For each formulation, dissolution time was recorded for three cakes and the mean dissolution time and standard deviation (SD) were calculated.

Lyophilized sucrose without additives dissolved very quickly. Lyophilized free PEG also dissolved rapidly. The dissolution time for cakes containing PEGylated rhGH analog was reduced to a third of that for cakes containing non-pegylated protein and free PEG (rhGH/PEG). A decrease in dissolution time in these cases is likely to be caused by PEGylation. It is known that PEGylation changes the surface properties of protein and increases protein solubility. The dissolution time of co-lyophilized PEGylated protein (PEGylated rhGH analog/sucrose (30:30:25) was shorter than co-lyophilized non-pegylated protein (rhGH) in the same amount of sucrose [rhGH/sucrose (30:0:25)], with the former being 1.5 times more disordered than the latter. Hence, the results showed that PEGylation reduces the dissolution time of the cake by increasing the degree of solid-state disorder. The higher the heat of interaction with water (i.e., degree of amorphicity), the shorter the dissolution time, until the dissolution time seemed to reach a plateau, when the solid was completely disordered. Parameters such as surface area and solubility are two of the most important parameters for dissolution rate (and thus dissolution time) of drugs. It has been suggested that the extent of solubility enhancement is closely related to the amount of amorphous material in the product [147]. An increase in apparent solubility would lead to an increase in initial dissolution rate (and thus a decrease in initial dissolution time).

A study carried out by Park et al. [148] compared the in vitro release property of mono-PEGylated growth hormone releasing peptide-6 (mono-PEG-GHRP-6) microspheres with native GHRP-6. The study was performed in 0.1 *N* phosphate buffer, pH 7.4, containing 0.02% Tween 80 and sodium azide at 37 or 55°C. The release profile at 55°C was carried out to observe drug release under accelerated conditions. At a specific time intervals samples were withdrawn, centrifuged, and the supernatant was analyzed by HPLC. It was found that the rate of drug release from microspheres decreased with increasing size of the PEG attached to GHRP-6.

***Pharmacokinetics and Biodistribution*** PEGylation alters physicochemical properties of proteins and modifies their pharmacokinetic parameters which in turn affect pharmacodynamic response. These modifications are utilized to deliver therapeutic proteins more effectively with better absorption, sustained plasma concentration, longer half life, reduced immunogenicity, decreased adverse reactions, and improved patient compliance. Alteration in size of PEG chain also alters the biodistribution behavior of PEGylated protein. Thus, increased PEG molecular weight decreases renal clearance, restricts biodistribution, and improves bioactivity. However, it is limited to a particular mass after which no increase in bioactivity is observed. Influence of pharmacokinetics and pharmacodynamics effect of protein PEGylation is given in Table 10 [149].

A potential effective antidiabetic agent, glucagon-like peptide-1-(7–36) (GLP-1) is a glucose-dependent insulinotropic hormone. However, a major limitation of GLP-1 is its very short half-life in plasma, which is due to its degradation by dipeptidyl peptidase IV (DPP-IV) enzyme. Thus, in an attempt to improve its therapeutic efficacy and reduce the dose and dosage frequency, a novel PEGylated GLP-1 conjugate was prepared by Lee et al. [150]. In vitro characterization and in vivo pharmacokinetic parameters of mono-PEGylated GLP-1 were also determined. The concentration of GLP-1 in plasma samples was analyzed by ELISA. The pharmacokinetic parameters were determined by non-compartmental and two-compartmental analysis after subutaneous (sc) and intravenous (iv) administration to Sprague–Dawley rats. Half-life of GLP-1 after iv administration was found to be 2.6 min, whereas mono-PEGylated GLP-1 showed 10-fold increase in half life, 1.5 fold reduction in renal clearance, and 16-fold increase in mean residence time. Similarly, after sc administration mono-PEGylated GLP-1 showed 2-fold increase in $C_{max}$, 7.5-fold increase in AUC (area under the curve), and 2.5-fold increase in half life as compared to GLP-1.

Owens et al. [151] reviewed the process of opsonization, biodistribution, and pharmacokinetics of polymeric nanoparticles and reported PEGylation to be the generally preferred method to prevent the nanoparticle detection by mononuclear phagocytic system (MPS) of

**TABLE 10 Pharmacokinetic and Pharmacodynamic Effect of Protein PEGylation**

| Sl. No. | Molecule | Pharmacokinetic Effect | Pharmacodynamic Effect |
|---|---|---|---|
| 1. | Interferon-α2a | Sustained absorption (subcutaneous first-order reaction)<br>Increased half-life (from 3–8 h to 65 h)<br>Decreased volume of distribution (from 31–73 to 8–12 L)<br>Decreased systemic clearance (from 6.6–29.2 to 0.06–0.10 L/h) | In vivo antiviral activity increased 12–135 times<br>Antitumor activity increased 18-fold<br>Improved sustained response to chronic hepatitis C |
| 2. | Interleukin-6 | Increased half-life (from 2.1 to 206 min) | Thrombopoietic potency increased 500 times<br>Decreased IgG1 production |
| 3. | Tumour necrosis factor (TNF) | Increased half-life (from 3 to 45–136 min) | Antitumor potency increased from 4 to 100 times<br>Decreased adverse events |
| 4. | Growth hormone releasing factor | | Potency increased 12- 55-fold, enhanced duration of action |
| 5. | Megakaryocyte growth and development factor | Increased half-life (10-fold) | In vitro activity increased 20-fold |
| 6. | Brain-derived neurotrophic factor | Increased half-life 5-fold (from 10 to 50 min)<br>Decreased clearance 2.6-fold (from 5.5 to 1.9 mL/min/kg)<br>Increased volume of distribution 1.7-fold (from 80 to 135 mL/kg) | |
| 7. | Asparaginase | Increased half-life 18-fold (from 20 to 357 h)<br>Unchanged volume of distribution<br>Increased AUC 26-fold (from 0.4 to 10.2 IU/mL/day<br>Decreased clearance 17-fold (from 2196 to 128 mL/m$^2$/day | |
| 8. | Suproxide dismutase | Increased half-life > 150-fold (from 3.5 to 540–990 min) | |
| 9. | Lactoferrin | Increased half-life 5- to 20-fold (from 3 to 15–60 min) | |
| 10. | Streptokinase | Increased half-life 1.7- to 5-fold (from 4 to 7–20 min) | Decreased antigenicity |
| 11. | Interleukin-2 | Increased half-life up to 6-fold (from 44 to 57–256 min)<br>Decreased clearance up to 10-fold (from 1.15 to 0.11–0.97 mL/min)<br>Unchanged volume of distribution | |

the body. The authors have discussed various methods to analyze in vitro and in vivo biodistribution and clearance of PEGylated conjugates. The in vitro methods are flow cytometry and cell-associated fluorescence measurements whereas in vivo biodistribution studies in animal models employ $^{14}$C radiolabeling or encapsulated indium histological studies.

***Stability of PEGylated Product*** Changes in the surface structure by chemical modification can impart useful and required properties to proteins. Highly flexible, well-defined chemistry and amphipathic properties of PEG make it a suitable polymer for carrying out chemical modifications in proteins [152]. Many methods, including immobilization, site-directed mutagenesis, chemical modification, and cross-linking have been described for protein modification [153].

Christakopoulos et al. [154] modified the surface of the low-molecular-weight endoglucanase of *Fusarium oxysporum* by covalent protein PEGylation with PEG

derivatives specific for lysine or cysteine attachment. The authors studied the effect of these modifications on pH stability.

The pH stability was determined by incubating the enzyme in the pH region 7.0–12.0, at 30°C for 24 h and measuring the residual activity at pH 7. The following buffering systems were used: 0.1 *M* phosphate (pH 6–8), 0.1 *M* Tris–HCl (pH 9.0), 0.1 *M* glycine–NaOH (pH 10), 0.1 *M* KCl–NaOH (pH 11–12).

*Effect of pH on PEGylated Protein Stability* At pH 12, 25°C temperature, and 24 h incubation time, the native enzyme (endoglucananase) was completely inactivated while 66 and 73% of the initial activity remained in two different PEG-modified endoglucanase. The modified endoglucanase showed enhanced stability due to the buffering action created against denaturation of proteins by the long PEG chains present with the copolymer modifiers such as SS–PEG (succinimidyl succinate–PEG) and Mal–PEG (maleimide–PEG) [155].

The effect of reaction pH on PEGylation of rh-interleukin-10 with histidine was investigated by Wylie et al. [126, 156]. In this study, mono-PEGylated interferon was prepared by reaction at pH 6.5 and 8.6. The sample created at pH 6.5 was stored at pH 6.8 and ambient temperature for 30 days. By SE-HPLC, only 4% was dePEGylated to unmodified interferon. At pH 8.6, however, 22% of mono-PEGylated interferon was dePEGylated only after 24 h. Thus, whereas the PEGylated isomer is more labile under basic conditions, it is stable at physiologic pH. Similarly, rh-interleukin-10 was PEGylated with succinimidyl carbonyl-PEG (SC–PEG) at pH 6.5 and 8.6. The products were assayed for stability in the presence of neutral hydroxylamine. For the pH 6.5 reaction, 50–60% of the product was cleaved by aminolysis with neutral hydroxylamine. But for the reaction at pH 8.6, only 10% was labile to this reagent. The combined results of interferon and rh-interleukin-10 suggested that the effect of reaction pH is largely unaffected by protein structure. Thus, control of reaction pH provides an effective means for rational design of PEGylated biological drugs.

*Effect of PEGylation Site on Protein Stability* Small structural changes in polypeptides can influence their physicochemical properties, biological activity, and potency. Most of the peptides or proteins are sensitive and prone to degradation by variations in chemical, thermal, and enzymatic changes leading to shorter biological half-life, poor efficacy, loss of potency, and changes in their physicochemical properties. PEGylation is widely applied to improve the resistance of polypeptides toward degradation, thus increasing their half life, improving their efficacy, reduced immunogenicity, increased solubility, and low toxicity. On PEGylation, even receptor binding affinity and distribution of polypeptides from blood to the target tissues and restricted due to increase in the molecular size by PEGylation. Therefore, proteins or peptides with selective and specific sites for PEGylation are indispensible for stable, potent, and effective therapeutic agents.

Lee et al. [157] separated, purified, characterized, and evaluated the effects of PEGylation site on the biological stability of three positional isomers of mono-PEGylated salmon calcitonins (mono-PEG-sCTs) in rat kidney homogenates. Stability analysis of sCT and mono-PEG-sCTs was carried out by radiolabeling (chloramine T method) and column switching reverse-phase HPLC. The degradation half life of these positional isomers increased in the order of the N terminus (125.5) < $Lys^{11}$ (157.3) < $Lys^{18}$ residue-modified mono-PEGylated sCT (281.5 min) over the native sCT (4.8 min). Hence, $Lys^{18}$ residue-modified mono-PEGylated sCT was found to be most stable which suggests that a selective and specific modified site on the protein molecule leads to higher stability as compared to those with many available sites for protein PEGylation.

*Effect of PEG Molecular Weight on Protein Stability* Lee et al. [61] evaluated the effect of PEGylation on in vivo and in vitro stability and biological activity of epidermal growth factor (EGF). For in vivo studies native EGF, PEG5k-EGF, and PEG2k-EGF were injected intravenously in the tail vein of mice. After a specified time both mouse kidneys were isolated, washed, and homogenized in PBS. The homogenate was centrifuged and the supernatant was analyzed for residual EGF as a function of time using a human ELISA kit. It was observed that PEGylation increased the circulation half-life about fourfold with PEG5k-EGF having the longest circulation time followed by PEG2k-EGF and native EGF. This order could be dependent on the chain length of PEG as a higher molecular weight of PEG decreased the glomular filteration rate and resisted proteolytic digesion. In this case, PEG5k-EGF and PEG2k-EGF were prepared by using PEG-propionaldehyde with molecular weights of 5000 and 2000 Da, respectively. The amount of residual protein in vitro was determined by incubating EGF and PEGylated EGF with kidney homogenates of mice for a specific time and consequently analyzing the supernatant samples. The residual amount of PEG5k-EGF and PEG2k-EGF were 88 and 50%, respectively, whereas native EGF degraded rapidly. Also, PEG5k-EGF maintained its original structure even after 10 h incubation with tissue homogenates. These results suggested higher stability of PEGylated EGF both in vivo and in vitro.

*Effects of PEG Conjugation on Insulin Properties* According to a study carried out by Hinds et al. [156], electrophilically activated derivatives of low-molecular-weight mPEG were chemically coupled to insulin, through its amino groups, at phenylalanine-B1 or lysine-B29 positions, with an amide bond being formed between the polymer and protein. The site specific attachment of mPEG to insulin significantly enhanced its resistance to aggregation. In addition, the PEGylated insulin was almost free from immunogenicity, allergenicity, and antigenicity. The modified conjugates remained in the systemic circulation for longer duration than unmodified insulin on sc administration.

*Effect of Thermal Modification on PEGylated Protein Stability* Two methods have been reported by Abuchowsky et al. to compare thermal stability of proteins and their PEGylated forms [3]. For this study, catalase was covalently attached to mPEG-1900 with 43% modification of amino groups to form PEG-1900–catalase. Similarly, catalase with PEG-5000 attached to 40% of the available amino groups formed PEG-5000–catalase. According to the first method, catalase and PEG-1900–catalase were maintained at a fixed temperature for 5 min followed by rapid cooling to room temperature and assay. The results revealed denaturation of catalase and its PEG-conjugated forms at around 55°C with PEG having no role in prevention or delay of denaturation at high temperature.

In the second method, catalase and PEG-5000–catalase were exposed to different temperature conditions, and samples from each condition were assayed by the perborate method. Maximum activity was shown by catalase at around 40°C, higher than that of PEG-5000–catalase. In this case, PEG-5000–catalase seemed to destabilize catalase structure, whereas low temperature near 0°C increased the activity of catalase and PEG-5000–catalase.

*Application of the Bioanalyzer to Stability Studies of PEGylation* In a different stability study [142], aliquots of RP–PEG5000 (recombinant protein–PEG5000), stored at −70°C for either 1 or 13 months, were compared. PEGylated product stability was preserved during the extended storage period. Both of the predominant peaks after 1 and 13 months contained 9 and 10 PEGs. Further MS data with these same samples confirmed the stability of frozen PEGylated RP. In this manner, the utility of the bioanalyzer for assessing PEG stability on the RP–PEG5000 molecule was demonstrated.

## 10 BIOPEGYLATION

### 10.1 Biosynthesis of PHA–PEG Natural Synthetic Hybrids (Polyhydroxyalkanoates)

Polyhydroxyalkanoates (PHAs) are polyesters family synthesized microbially and sequestered intracellularly under environmental stress and excess carbon conditions [158]. They are white refractile inclusion bodies that act as carbon reserves and ion sinks. A well known PHA derivative is polyhydroxybutyrate (PHB) which is a homopolymer with 3-hydroxybutyrate monomer (HBA). These are ketone bodies, which are also synthesized in mammalian cells during prolonged or periodic starvation and diabetes mellitus. Trace amount of PHB is also found in mammalian cell membranes involved in transport functions of the cells. It has been studied as a biomaterial for medical devices and failed in spite of its biocompatibility. This was due to its inherent physicochemical properties such as high crystallinity, brittle nature, and in vivo degradation tendency. Modifications with copolymers to overcome these drawbacks have been attempted successfully. Copolymerisation of PHB with hydroxyvalerate (HV) resulted in a biocompatible and biodegradable polymer, P (HB-*co*-HV), which when synthesized in different microorganisms produced an array of PHAs with different monomeric components. These provided many choices to select from brittle and crystalline to flexible and elastomeric. However, formation of different PHAs depends on the species of microorganisms as some produced PHAs with short chain length, whereas others produced medium or longer chain lengths. As an alternative, Gross et al. used PEG to increase 4-HBA units and to form novel PHAs with diverse monomeric units, considering biocompatibility and utility of PEGs in biomedical applications. PEG 200 (1–4%) was loaded in Erlenmeyer flasks with *Ralstonia eutropha* cultures to produce P (3HB-*co*-4HB). The results provided control over PHA monomeric composition with increase in the main carbon source, 4-HBA in sclPHA (short chain length polyhydroxyalkanoates). It was also observed that the lower the PEG molecular weight the greater was the PHA molecular weight reduction. Thus, PEGs also offered some control over PHA molecular weight. PEG molecules also promote PHA chain scission. The $H^1$ and $C^1$ NMR analysis of PEG-modulated PHAs confirmed PHA chain termination by PEG. This formed a new class of natural synthetic hybrid block copolymers with PHA chains "end capped" with PEG. In a review on PHA and PEG conjugation, Foster proposed the term "BioPEGylation" for such copolymerization to distinguish their biological incorporation and to relate their functional and structural similarity with

"PEGylation," the term that was coined by Harris et al. [48].

### 10.2 Applications of PEGylated PHA: BioPEGylation

BioPEGylation is up and coming field in terms of PEG–PHA hybrids with high potential to control the composition and molecular mass. It is also a simple method to control physicochemical properties of PHAs. Even crystallization properties of PHAs are also altered by PEG–PHA bioconjugation, which leads to formation of disordered microporous honeycomb films. These films have been reported to have biotechnological and biomedical applications such as biomolecular immobilization. BioPEGylation also reduce surface hydrophobicity of PHB determined by significant decrease in the contact angle. Thus, solubility of hydrophobic pharmaceutical agents can also be improved by the BioPEGylation technique.

## 11 PEGYLATION IN NOVEL DRUG DELIVERY SYSTEMS

### 11.1 PEGylation of Microspheres

Gbadamosi et al. [159] generated a heterogeneous population of surface PEGylated polystyrene microspheres [159]. The procedure followed was a two step process by which the polystyrene particles were PEGylated with mPEG-5000. In this process, the polystyrene particles were first treated with BSA and then followed by the conjugation of the nucleophiles of the adsorbed BSA monolayer with the molar excess quantities of cyanuric chloride-activated mPEG-5000. On characterizing the PEGylated particles by hydrophobic interaction chromatography, particle electrophoretic mobility was measured in a defined field. It was observed that the formulation was composed of two different entities of similar size distribution but with different surface hydrophilicity. The minor population (20%) consisted of the entities with predominant surface mPEGs in a mushroom regime. This population of the particles produced was prone to phagocytosis and hence did not exhibit prolonged circulation times in the blood. On the other hand, the major population (80%) consisting of microsphere entities having a predominant surface of mPEG molecules as high-density mushroom brush intermediate or brush configuration were most resistant to phagocytosis and poorly activated the human complement system [159].

Out of the various methods reported, therapeutic embolization is a well-estabilished method for the treatment of many vesicular lesions, including hemorrhages, arteriovenous malformations of various origins, and hypervascular tumors. This method is based on the principle of keeping the embolic region away from the blood circulation. This method has a limitation due to the development of a vascular network around the pathologic area, which has a tendency to nourish the isolated region. This revascularization is due to the presence of giant cells (macrophages). The most effective results for the obliteration of blood vessels have been obtained by using calibrated, soft, compressible, and relatively hydrophilic microspheres of controlled shape and dimensions. The nonbiodegradeable polymer used for the preparation of microspheres was derived from polyacrylamide called "Trisacryl." Madani et al. [160] PEGylated microspheres designed for embolization, defined as GF2000-Trisacryl MS (GF-MS) and DEAE-Trisacryl MS (DEAE-MS), using (3-amino propyl)triethoxy silane as the coupling agent. Indomethacin was loaded into both PEGylated and non-PEGylated DEAE-MS, displaying ion exchange ability. A complement activation test was performed in this case similarly as mentioned above. It was observed that the PEGylated GF-MS and DEAE-MS activated the complement system less than the naked microspheres. It was also observed that loading PEGylated DEAE-MS with indomethacin suppressed the complement activation. This inhibiting role showed that PEGylation as well as loading the microspheres with anti-inflammatory drug had a compact effect on the interaction of microspheres with blood proteins [161].

### 11.2 PEGylation of Liposomes

PEGylation of liposomes has provided several advantages in the development and design of novel drug delivery systems (NDDS). Liposomes without PEG were cleared rapidly from the blood and accumulated preferentially in the liver and the spleen. In a study reported by Lee et al. [162] it was observed that the modification of liposomes using PEG resulted in steric hindrance to the phagocyte system and hence prolonged blood circulation time. A reduction in radiolabeling efficiency (RE) was also observed when the glutathione method was used for the radiolabeling of liposomes. Different liposomal formulations were prepared with different extent of PEGylation, and their effect on in vivo biodistribution of liposomes in Wistar rats, and RE with technetium-(99m) ($^{99m}$Tc) was observed. Liposomes were prepared and PEGylated with egg phosphatidylcholine (egg PC, 1.85 mol%), cholesterol (1.0 mol%), and distearoylphosphatidylethanolamine-*N*-[polyethylene glycol] (DSPE–PEG). Preformed liposomes were radio-

labeled with $^{99m}$Tc-hexamethylpropylene-amine oxime [(99m)Tc-HMPAO] complexes. Sephadex G-15 column was used to check the labeling efficiency and stability. Biodistribution studies of $^{99m}$Tc-liposomes after iv injection was observed in Wistar rats [162].

Vyas et al. [163] observed that encapsulation of IFN-α in multivesicular liposomes (MVLs) and PEGylating it further affects the half-life of the IFN-α. They conjugated the IFN-α with mPEG and then purified them with size exclusion chromatography. A double emulsification technique followed by evaporation of organic solvents from chloroform ether spherules suspended in water was the method used for the preparation of PEGylated IFN-α encapsulated multivesicular liposomes. In vitro antiviral activity of PEGylated IFN-α-2a was found to be 87.9% of the unmodified IFN-α. This study, however, confirmed that multivesicular liposomes can be exploited as a long-acting or sustained-release delivery system using a combination of PEGylation and encapsulation technique for controlled delivery of IFN-α [163].

Very recently, work is going on for the development of photodynamic therapy (PDT) with a photosensitizer and Laser for the treatment of various types of cancers such as lung cancer, gastric cancer, bladder cancer, and cervical cancer. PDT is a novel approach for the destruction of cancerous cells or the malignant tissue. This approach involves the systemic or topical administration of nontoxic dyes known as photosensitisers. Then the lesion is exposed to the light in the visible range (usually red). The photosensitizers on the absorption of light produce free oxygen radicals, which are cytotoxic and thus kill malignant tissue. Sadzuka et al. [164] prepared photofrin liposomes (PF-Lip) with dimyristoylphosphatidylcholine, dimyristoylphosphatidylglycerol, and cholesterol, and they were further PEGylated (PF-PEG-Lip) to enhance the efficacy of PDT. It was observed that the trapping ratio of PF and particle size was unaffected by the PEGylation of liposomes. Phototoxicity was enhanced by liposomalization, especially PEG modification. However, it was also observed that the PF-PEG-Lip inhibited the uptake of photofrin into tumor cells. The amount of singlet oxygen from the photofrin solution (PF-sol) and each liposome was PF-PEG-Lip ≒ PF-Lip > PF-sol. PF-PEG-Lip showed a lower release level of photofrin than that of PF-Lip. Formation of a fixed aqueous layer on the liposome membrane by PEGylation made it stable in the state of PF-PEG-Lip [164].

Another study has been carried out on the PEGylated liposomal vesicles for the delivery of oligonucleotides intracellularly. Remaut et al. [165] observed that the PEGylated liposomal vesicles provided a better way to avoid the unspecific uptake by the reticulo endothelial system (RES). PEGylation of the liposomes, by incorporating PEG at the surface, avoided the unspecific uptake by the RES. PEGylation was shown to have a clear benefit on the systemic level, but its benefits on the delivery efficacy of liposomes at the intracellular level is yet to be proved. The authors compared the intracellular distribution of non-PEGylated and PEGylated liposomes, with special attention to the integrity of the oligonucleotides they were carrying. After uptake in the cells, the non-PEGylated liposomes efficiently escaped from the endosomes, thereby releasing phosphodiester oligonucleotides (PO-ONs) in the cytoplasm of the cells. The PO-ONs were, however, rapidly degraded in the intracellular environment. In contrast to non-PEGylated liposomes, PEGylated liposomes failed in protecting the PO-ONs they were carrying, leading to rapid degradation of the PO-ONs in the endosomal compartment. Furthermore, the PEG chains inhibited the endosomal escape of the degraded ONs. These intracellular findings explained the reasons for the failure of PEGylated liposomes in establishing an antisense effect.

### 11.3 PEGylation of Charged Polymer Photosensitizer Conjugate

As discussed earlier, PDT is a novel approach for the destruction of cancerous cells or malignant tissue. In another study Hamblin et al. [166] studied the conjugation of photosensitizers to macromolecular delivery vehicles that are designed to improve their performance by increasing specificity and uptake in tumors or other pathological lesions, favorably altering pharmacokinetics or biodistribution or decreasing phototoxicity to normal tissue. The authors investigated the effect of PEGylation on the uptake and phototoxicity of poly-L-lysine chlorine conjugates with either cationic or anionic charges in two types of cell lines, that is, human ovarian cancer cells and mouse macrophages. It was observed that the PEGylated cationic conjugate was less aggregated, consumed less oxygen, and had reduced cellular uptake. But it was also observed that the phototoxicity corrected for cellular uptake increased three- to fivefold. On the contrary, the anionic succinylated conjugate on PEGylation became more aggregated, consumed similar amounts of oxygen, and had higher cellular uptake. The anionic conjugate showed the highest relative phototoxicity toward both the cell lines and it decreased most toward the macrophages after PEGylation. The authors concluded that the PEGylation reduced the amount of oxygen consumed per chlorine molecule when photosensitized cells were illuminated. These in vitro studies suggested that PEGylation altered the phototoxicity of polystyrene (PS) conjugates

depending on the effect produced on the aggregation state [166].

### 11.4 PEGylation of Micelles

Various studies have been carried out to develop a micellar system for various drugs to enhance their circulation time and thereby improve their pharmacokinetic and therapeutic properties. Dhanikula and Panchagnula [167] prepared the micelles of paclitaxel by two methods. The first method involved physical incorporation of paclitaxel into poloxamer micelles wherein poloxamer 407 and paclitaxel were dissolved in chloroform. The solvent was removed by rotary evaporation at 60°C under vacuum. The resulting matrix film was hydrated to yield micelles containing paclitaxel. The other method involved an initial generation of oligomer with acid chloride groups to esterify both paclitaxel and poloxamer, leading to the formation of a conjugate. The oligomer (300–500 μL in dry acetonitrile) was transferred into a 2-mL microcentrifuge tube containing poloxamer 407 and paclitaxel dissolved in dry acetonitrile. After closing the tube to prevent access of moisture, it was left for 10–12 h at room temperature with occasional agitation for conjugation of poloxamer as well as drug with acid functional groups of oligomer. About 500 μL of water was added in order to quench the reaction and precipitate unreacted oligomer. After centrifugation to settle the precipitate, supernatant (acetonitrile–water phase) was separated and dried at 45°C for 12–15 h by centrifugal evaporation. The product thus obtained on drying was reconstituted in phosphate buffer (pH 7.4), which yielded paclitaxel-loaded micelles. It was also observed that the physical stability and payloads of colloidal carrier systems are generally low while dealing with molecules of high molecular weight such as paclitaxel. It was also observed that the PEGylation of the micelles loaded with the drug improved the aqueous solubility of the drug [167].

### 11.5 PEG-Coated Emulsions

Various studies have revealed that PEGylation of the oil-in-water emulsions prolongs the circulation time of drug entrapped in emulsions and shows enhanced accumulation in the carcinoma cells. In a study conducted by Rossi et al. [168] oil-in-water emulsions were developed (100–120 nm in diameter), and the surface properties of the emulsions were correlated with blood residence time and accumulation into neoplastic tissues by passive targeting. The authors investigated the effect of various phospholipid and sphingolipid emulsifiers, hydrogenated soyabean phosphatidylcholine (HSPC) and egg sphingomyelin (ESM), in combination with polysorbate 80 (PS-80) and 1,2-distearoyl-sn-glycero-3-phosphatidylethanolamine (DSPE)-PEG lipids of various PEG chain lengths and structures in prolonging circulation time and enhancing accumulation into B16 melanoma or C26 colon adenocarcinoma. The relationship between amphiphile molecular packing at the air–water interface on emulsion stability upon dilution in albumin and circulation longevity in vivo was also explored. PEGylation of the droplet surface with 10–15 mol% of DSPE–PEG 2000 or 5000 enhanced the circulation time of the emulsions. However, accumulation was only observed in the C26 tumor model. The tighter molecular packing observed with ESM/PS-80 monolayers at the air–water interface compared to HSPC/PS-80 correlated with improved emulsion stability in vitro, however, enhanced circulation time in vivo was not observed. The authors concluded that the understanding of the relationships between composition and performance will result in improved emulsion-based drug delivery vehicles for cancer therapy [168].

### 11.6 PEGylated Nanoparticles

Cationic polylactic acid (PLA) nanoparticles (NPs) have emerged as an important tool to replace viral vectors for gene delivery because of their biocompatibility and biodegradability. The only limitation faced by them is the fact that they are not capable of prolonging gene transfer and high transfection efficiency. Chen et al. [169] used copolymer methoxypolyethyleneglycol–PLA (MePEG–PLA), PLA, and chitosan (CS) to prepare MePEG–PLA–CS NPs and PLA–CS NPs by a diafiltration method and prepared NPs/DNA complexes through the complex coacervation of NPs with the pDNA. The authors evaluated the transfection efficiency of MePEG–PLA–CS versus PLA–CS NPs. The MePEG–PLA–CS NPs had a zeta potential of 15.7 mV at pH 7.4 and size under 100 nm, while the zeta potential of PLA–CS NPs was only 4.5 mV at pH 7.4. Electrophoretic analysis suggested that NPs could protect the DNA from nuclease degradation. The cell viability assay showed that NPs exhibited a low cytotoxicity to normal human liver cells. The pDNA being carried by MePEG–PLA–CS NPs, PLA–CS NPs, and lipofectamine could enter and express in COS7 cells. However, the transfection efficiency of MePEG–PLA–CS/DNA complexes was better than PLA–CS/DNA and lipofectamine/DNA complexes as observed by inversion fluorescence microscope and flow cytometry. Also, the transfection activity of PEGylated complexes was improved. The NPs were also tested for their ability to transport across the gastrointestinal mucosa in vivo in mice. In vivo experiments showed that MePEG–PLA–CS/DNA complexes had higher gene expression

in stomach and intestine of BALB/C mice (an albino strain of laboratory mouse from which a number of common substrains are derived) compared to PLA–CS/DNA and lipofectamine/DNA complexes. These results suggested that MePEG–PLA–CS NPs have favorable properties for nonviral gene delivery [169].

Many of the ocular diseases are due to the gene defect in the retina, and ocular gene delivery has appeared as a promising tool for the treatment of these disorders. It is well known that the blood–retina barrier and sclera prevent hydrophilic and high-MW drugs to reach the retina after systemic or topical application. Sanders et al. [170] overviewed the behavior of nonviral nucleic acid NPs (lipoplexes) in vitreous and on PEGylation strategies that improve the behavior in vitreous, without compromising with their transfection capacity. It was observed that the intravitreal injection of nonviral nucleic acid NPs was safe and a promising approach in ocular gene transfer.

Yoncheva et al. [171] performed the experiments to test the bioadhesive potential and intestinal transport of PEGylated poly(anhydride) NPs. The authors PEGylated the NPs based on poly(methyl vinyl ether-*co*-maleic anhydride) with two hydroxyl-functionalized PEGs (PEG and methoxy PEG, mPEG) and two amino-PEGs (DAE–PEG and DAP–PEG). The resulted NPs were observed to have reduced negative charge in comparison to the non-PEGylated particles when in vivo tests were performed. Higher bioadhesive potential was observed in the case of PEG-NP and DAE–PEG-NP, which was attributed to the flexibility and specific properties of the surface "brush" layer of these particles [171].

## 11.7 PEG-Based Micelles as Diagnostics

***Diacyl PEG Micelles*** A number of studies have revealed that the stability of micelles depends on the strength of van der Waal's interactions between hydrophobic blocks and the molecular size of the hydrophilic block. Use of lipid moieties as hydrophobic blocks capping PEG chains has the advantage of particle stability in comparison to the conventional amphiphilic polymer micelles. This is due to the existence of two fatty acid acyls that act as a major contributor to an increase in the hydrophobic interactions between the polymeric chains in the micelles core.

Diacyllipid-PEG conjugates were introduced as polymeric surface modifiers for liposomes. The diacyllipid-PEG molecule represents a characteristic amphiphilic polymer with a bulky hydrophilic (PEG) portion and short but extremely hydrophobic diacyllipid part, and diacyllipid-PEG conjugates were found to form micelles in an aqueous environment [172].

***Polymeric Micelles*** Polymeric micelles are a special type of micelles formed from copolymers consisting of hydrophilic as well as hydrophobic monomer units. The micelles are composed of the core of the hydrophobic chains stabilized by the corona of hydrophilic polymeric chains. The decrease of free energy of the system due to removal of hydrophobic fragments from the aqueous surroundings with the formation of micelle core stabilized with hydrophilic blocks exposed into water is the major driving force behind self-association of amphiphilic copolymers. The lower is the critical micellar concentration (CMC) value of a given amphiphilic polymer, the more stable are micelles even at low concentration of an amphiphile in the medium [172].

PEG is frequently used to build hydrophilic block(s) of micelle-forming copolymers since this polymer is water soluble and serves as an efficient stearic protector for various microparticulates (such as micelles, liposomes, nanoparticles, and nanocapsules) in biological media. Though a number of other hydrophilic polymers may be used to make corona blocks, PEG remains the hydrophilic block of choice [172].

Bae and co-workers [173] studied the in vivo behavior and biodistribution of therapeutic polymeric micelles formed by the copolymer of PEG and poly(aspartic acid) (PEG-*b*-PAA) with covalently bound adriamycin. The approach involved the covalent attachment of adriamycin to PAA of PEG-*b*-PAA (PEG–PE) copolymer resulting in the formation of an amphiphilic AB-type copolymer. This copolymer was able to form polymeric micelles with the hydrophobic block making up particle's core, while the PEG block formed a surrounding water-soluble shell. Micelles formed from this conjugate were stable in vivo and their disintegration took hours. AB-type amphiphilic block copolymers of PEG (MW of 12 kDa) and poly(aspartyl adriamycin) with 20 aspartyl adriamycin units demonstrated blood half-life in mice >5 h, indicating thus a substantial increase in micelle stability [173].

## 11.8 Use of PEGylation in Scaffold for Tissue Engineering

Hydrogels formed by photochemical-induced cross-linking contain large water contents and have mechanical properties similar to those of soft tissues. In addition, hydrogels have high permeability for oxygen, nutrients, and other water-soluble metabolites. Another advantage of photogenerated hydrogels as opposed to natural physical gels such as alginate is that their material properties can be more easily adjusted to fit the desired application.

These have emerged as a significant biomaterial in applications such as scaffolds for tissue engineering,

drug delivery carriers, thrombosis prevention devices, postoperative adhesion promoters, and coating for biosensors. The photopolymerization process allows the hydrogel to be generated in vitro or in vivo from a low viscosity solution of monomer, oligomer, or low molecular mass functional polymer (macromer) by a free radical pathway in a minimally invasive manner.

***Tyrosine PEGylated Polyether Carbonate (PEC)*** Polymeric scaffolds for tissue reconstruction, development of artificial organs, degradable membranes for the prevention of surgical adhesions, and intra-arterial coatings for the prevention of thrombosis or restenosis are some of the examples for new applications of medical implants. These advanced applications require degradable biomaterials whose physicomechanical, chemical, and biological properties can be closely matched to a wide range of narrowly defined, application-specific requirements.

Biomedical engineers and medical device designers have employed almost exclusively degradable polyesters derived of α-hydroxy acids such as poly(glycolic acid), poly(lactic acid), and polydioxanone. Among these polymers, tyrosine-derived polycarbonates have been studied most extensively and have been found to be tissue compatible, strong, tough, hydrophobic materials that degrade slowly under physiological conditions. These materials appear to be most suitable for use in orthopedic implants [174].

Other medical applications such as drug delivery, nonthrombogenic coatings, vascular grafts, scaffolds for wound healing, and artificial skin require materials that are more hydrophilic, softer, and that degrade faster than the available tyrosine-derived polycarbonates. To address these needs, tyrosine-derived diphenolic monomers were copolymerized with blocks of PEG, resulting in a new class of poly(ether carbonate)s.

Yu et al. [125] prepared tyrosine–PEG–derived poly(ether carbonate)s by condensation copolymerization with phosgene. The resulting polymers were random copolymers with average molecular weights from 40,000 to 200,000 Da. Chemical structure and purity were confirmed by NMR and FTIR spectral analysis. They established the general structure–property correlations. The glass transition temperature decreased with increasing PEG content and increasing pendent chain length. When higher molecular weight PEG blocks was used, the glass transition temperature increased relative to identical polymers having shorter PEG blocks. The tensile modulus increased with decreasing PEG content, decreasing pendent chain length, and when longer PEG blocks were used. Water uptake and the rate of backbone degradation increased with increasing PEG content [174].

***PEG–Fibrinogen Hydrogel*** Various types of biological materials and synthetic polymers are used to fabricate tissue engineering scaffolds. Biological materials provide biofunctional signals and interact well with cells, whereas, synthetic polymers provide precise control over their structural properties. A biosynthetic hybrid scaffold comprised of a fibrinogen backbone and cross-linked with difunctional PEG side chains was prepared by Almany and Seliktar [175]. Denatured fibrinogen fragments were PEGylated with PEG-diacrylates, mixed with photoinitiator, and exposed to UV light to form a hydrogel material in the presence of a cell suspension. This method of hydrogel preparation was unique because its mechanical properties were highly malleable while the biological functionality was maintained by the backbone of the polymeric network. The PEG–fibrinogen material represents one of a new generation of tissue regeneration scaffolds, which are suitable for forming three-dimensional structures with distinct biological and structural properties. The design of the material will also permit precise control over degradability, biofunctionality, and structural properties, depending on the clinical need [175]. The elastic modulus of the PEG–fibrinogen hydrogel is dependent on the molecular weight of the PEG constituent and proportional to the percent polymeric composition. Smooth muscle cells demonstrate the ability to proteolytically penetrate through the hydrogel material and form interconnecting networks of cells.

***PEG Urethane Dimethacrylate Hydrogels*** Several types of photopolymerizable hydrogels, including those derived from PEG diacrylate and dimethacrylate derivatives and PEG copolymerized with fumarate groups, have been investigated for use as biomaterials. Well characterized PEG dimethacrylates (PEGDM) and similar reactive PEG derivatives are some of the interesting model systems because, although PEG alone is bioinert, it can be easily modified to become bioactive. In addition, hydrogels from PEGDM and their copolymers and derivatives have been shown to be promising as scaffold materials.

The physical properties of hydrogels are still difficult to predict by theories due to nonidealities of gel formation. Well-defined model materials are necessary for the preparation of hydrogels with highly reproducible and easily adjustable properties [176].

***Single-Chain Glyco sFv Proteins*** Single-chain sFv proteins have become the antigen-binding format of choice because of its single polypeptide design. They normally lack asparagine-linked glycosylation. Nowadays many therapeutic agents employ the advantageous conjugation chemistry or the targeting proper-

ties provided by the glycosylation. Wang et al. [177] found the newly formed sFv proteins on evaluation in *Pichia pastoris* for glycosylation efficiency, expression level, oligosaccharide chain length and composition, and affinity. It was also observed that the engineered attachment of N-glycans conveniently near the polypeptide C terminus was found to produce the optimal results. The glycosylated sFv mannose chains could be effectively conjugated to PEG, and the resulting conjugate displayed a 10-fold increased circulating life in mice. The potential to control polymer:sFv or drug:sFv molar ratios by site-specific conjugation may substantially improve the therapeutic efficacy of these minimal antigen-binding molecules [177].

## 11.9 PEGylation in Gene Delivery

***PEGylated Adenovirus*** Gene therapy is proposed as an alternative treatment for cancers of gastrointestinal tract, especially colorectal cancer, which has become the leading cause of cancer mortality in western countries. "Adenovirus is a suitable gene delivery vector for cancer because it is capable of producing high levels of gene expression rapidly and transiently and has been used in several clinical gene therapy protocols for this purpose" [178, p. 1444]. Formulation of adenovirus significantly improved the viral transduction of differentiated intestinal epithelial cells in vitro and in vivo. Reduction of intestinal motility and distension of isolated intestinal segments with large fluid loads have also improved adenovirus transduction efficiency in vivo.

Oral administration of adenoviral vectors for the gene delivery to the intestine is not popular despite of the above mentioned improvements. This is because of the following problems associated with it:

1. Adenoviral vectors are unstable at acidic pH and significant amount of dose loss had been observed, when it comes into contact with stomach contents.
2. Enzymes present in the gastrointestinal tract (GIT) may inactivate the virus because viral capsid proteins are prone to digestion in vitro.
3. Bile salts induce aggregation of adenoviral particles making them ineffective.

PEGylation of the adenoviral vectors comes with the solution to the above mentioned problem. Recombinant adenovirus was modified with mono-mPEG activated by cyanuric chloride, succinimidyl succinate, and tresyl chloride. Transduction efficiency was assessed on Caco-2 cells. In vitro stability of viruses in simulated gastric fluid, pancreatic fluid, and bile was assessed by serial dilution on 293 cells. Oral administration of $1 \times 10^{12}$ particles of unmodified or PEGylated virus to fasted Sprague–Dawley rats determined transduction efficiency in vivo. Results have shown that the titers of unmodified virus declined to undetectable levels after 40 min in simulated gastric fluid while the infectious titer of the modified vectors did not change for 3 h. Similar results were seen with simulated pancreatic fluid. PEGylation also enhanced adenoviral transduction efficiency in Caco-2 cells by a factor of 20. PEGylation-enhanced adenovirus transduction efficiency 10- to 40-fold in vivo in intestinal segments that do not express significant amounts of adenovirus receptors (jejunum, colon) with transgene expression located in the crypt regions. Hence, the authors concluded that the PEGylated adenoviruses are suitable gene delivery vehicles for oral administration [178].

***PEGylated Vesicular Stomatitis Virus G*** Lentivirus belongs to the family of retroviruses that includes human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2), simian immunodeficiency virus, feline immunodeficiency virus, and bovine immunodeficiency and equine infectious anemia viruses. They have generated great interest as vectors for gene therapy. In terms of gene delivery, they have all the conventional attributes of other retrovirus vectors, including stable integration of the transgene into the target cell genome. One disadvantage of vesicular stomatitis virus G (VSV-G) pseudotyped lentivirus vectors for clinical application is inactivation of the vector by human serum complement. To prevent this, Croyle et al. [179] conjugated monomethoxypoly(ethylene) glycol to a VSV-G-HIV vector expressing *Escherichia coli* β-galactosidase. The modification did not affect transduction efficiency in vitro and protected the vector from inactivation in complement-active human and mouse sera. PEGylation extended the circulation half-life of active vector by a factor of 5 and reduced the rate of vector inactivation in the serum by a factor of 1000. Pharmacokinetic profiles for the total number of virus particles present in the circulation were unaffected by PEGylation. Modification of the vector with PEG significantly enhanced transduction efficiency in the bone marrow and in the spleen 14 days after systemic administration of the virus. These results, in concert with the pharmacokinetic profiles, indicated that PEGylation does protect the virus from inactivation in the serum and, as a result, improves the transduction efficiency of VSV-G pseudotyped lentivirus vectors in susceptible organs in vivo [179].

***PEGylated Antibodies*** Recently, work has been done by various scientists on the PEGylation of antibodies and antibody fragments. PEGylation of antibodies has been used to reduce immunogenicity and increase the circulation half-lives. It has also been observed that the PEGylation of antibodies improved the targeting to tumors. The site-specific attachment of PEG to antibody fragments avoids the common and substantial losses in antigen binding and may lead to further improvements by maintaining binding affinity and homogeneity of product suitable for large-scale manufacturing [180].

## 12 RESEARCH UNDER PROGRESS

### 12.1 PEG-Acetylcholinesterase

Acetylcholinesterase (AChE) is a neuroenzyme that aids in the termination of impulse transmission in cholinergic synapses by rapid hydrolysis of the neurotransmitter acetylcholine. AChE is found in cholinergic neurons (dendrites, perikarya, and axons) with high concentration at the postsynaptic end-plate of the neuromuscular junction [181]. PEGylation has been used as a tool to extend the circulatory residence time of AChE by Kronman [182]. The authors attached PEG chains to primary amines in AChE using succinimidyl propionate-activated methoxy-PEG. Briefly, purified rHuAChE (5 μM) was incubated with PEG-20000 at a ratio of 30:1 (mol/mol) $[PEG]_0/[AChE\ primary\ amines]_0$ in 50 mM borate buffer, pH 8.5, for 2 h at room temperature. The chemically modified products were dialyzed extensively against PBS and analyzed on 6% SDS/PAGE gels. This resulted in a protective shield around the enzyme, thus impeding physical interactions between the PEGylated AChE and membrane-bound protein receptors. The antigenicity studies were carried out by incubating PEGylated-HuAChE in the presence of different amounts of mouse polyclonal anti-ChE antiserum and then precipitating with protein G–Sepharose beads. Residual ChEs activity in the soluble nonbound fraction was determined. It was observed that more than 90% of the PEGylated AChE activity remained in the supernatant following immune precipitation with the same volume of antiserum, attesting to the poor interactions of PEGylated AChE with anti-AChE antibodies. Thus, it can be concluded that the efficient appendage of PEG moieties to AChE indeed provided the enzyme with a protective "shield," which prevents its immunorecognition by antibodies. Moreover, this PEG shield conferred circulatory longevity to enzyme molecules, which was confirmed by administering the PEGylated enzyme to mice and monitoring its pharmacokinetic profile by determining residual AChE activity in blood samples removed at various time points. PEGylation of AChE affected elimination processes not only by increasing the overall molecular size of the modified protein but also by masking the modified enzyme in a manner that prevented molecular interactions with other proteins. In addition to these advantages, PEGylated enzyme retained the native property of AChE that is, protection against organophosphate poisoning. To confirm this, mice challenged with more than twice the lethal dose of Soman (organophosphate) were treated with AChE and PEGylated AChE, and it was observed that animals in both the groups survived. Moreover, the circulatory long-lived PEGylated AChE can confer superior protection to mice against organophosphate poisoning. These findings established PEGylation as an effective and safe means of improving the circulatory residence time and reducing the immunogenic potential of AChE [182].

### 12.2 PEG–Interferon

Interferon (IFN), a class of cytokines displaying a wide range of antiviral, antitumor, and immunomodulatory activities, has been successfully used as a therapeutic tool for a variety of diseases such as skin malignancies, hematologic proliferative diseases, viral infections, multiple sclerosis, and hepatitis B and C [183]. Interferons have been PEGylated in order to improve the pharmacokinetic properties and minimize the loss of IFN bioactivity. PEGylation was carried out by mixing IFN and PEG at 1:3 molar ratio in 50 m*M* sodium borate buffer (pH 8.0). The reaction was stopped after 2 h by adjusting the pH of the mixture to 4.8 with phosphoric acid. The pharmacokinetics of IFN and PEG–IFN were evaluated after a single intravenous or subcutaneous injection in rats. Blood samples were withdrawn at specified time points, and the serum samples were analyzed for interferon activity by cytopathic effect (CPE) assay. It was observed that the plasma half life of PEG-IFN increased as compared to native IFN due to a decreased rate of renal clearance of PEG–IFN. The in vitro antiviral activity of PEG–IFN was determined by CPE assay using Madin–Darby bovine kidney cells (MDBK) cells challenged with vesicular stomatitis virus. The PEGylated IFN showed reduced anti-viral activity vis-à-vis native IFN, but the prolonged in vivo half-life of PEGylated IFN has overcompensated for the decreased bioactivity, eventually leading to a markedly enhanced in vivo therapeutic efficacy [183].

The elimination $t½$ of IFN is short; hence the number of injections of the molecule required per day is more. Asselah et al. [184] observed that PEGylation of IFN increases the half-life, which in turn leads to reduction in the number of daily injectons, thus greatly enhancing the patient compliance. Souvignet et al. [185] also

reported that the conventional IFN plus ribavirin therapy for treatment of hepatitis C can be rendered more efficacious by employing a combination of PEGylated IFN plus ribavirin. The results were so promising that PEG–IFN and ribavirin combination therapy is currently the recommended standard for treatment of patients with chronic hepatitis C. The recommended treatment duration is 48 weeks for hepatitis C genotype I and 24 weeks for genotypes II or III [185]. Gupta et al. [186] recommended that the dose of PEGylated interferon needs to be adjusted in patients with renal insufficiency. The multiple-dose pharmacokinetic study showed that exposure to PEG–IFN is increased in patients with renal insufficiency due to reduced clearance. Hence, the doses of the drug should be reduced by 50% in patients with severe renal insufficiency and by 25% in those with moderate insufficiency [186].

The PEGylated interferons have also been reported to nullify the risk of developing thyroid dysfunction associated with the treatment with IFN plus ribavirin. In a study carried out by Tran et al. [187] monthly thyrotropin levels of 24 patients undergoing PEG–IFN and ribavirin therapy were observed and it was concluded that there were no symptoms of hypo- or hyperthyroidism. It was concluded that the PEG–IFN and ribavirin therapy is safe in hepatitis C.

### 12.3 PEG-Asparaginase

L-Asparaginase is an important chemotherapeutic agent used for the treatment of a variety of lymphoproliferative disorders and lymphomas, acute lymphoblastic leukemia. Some of the drawbacks associated with asparaginase therapy are high immunogenicity ranging from mild allergic reactions to anaphylactic shocks and very short half-life. Narta et al. [188] tried a number of chemical modifications of asparaginase to reduce such adverse effects, but he concluded that PEGylation was the best option. Antileukemic activities of the PEGylated preparation were tested in the L5178Y tumor-bearing BDF mouse model. Conjugation of enzyme to PEG succeeded in abolishing the drug's immunogenicity. The biochemical properties of PEG-asparaginase markedly differ from the native enzyme, namely apparent molecular weight is higher, and reactivity with specific antibodies is very low but increases if the drug is subjected to freeze–thawing cycles. In addition, the plasma half-life of 20 h of the native enzyme can be successfully increased to 357 h using PEGylation approach. Due to this property, the frequency of injection of the enzyme can be reduced from once in every 2 days to once in every 2 weeks [188]. The improvement in half lives of the enzyme upon PEGylation as observed in various laboratory animals is depicted in Table 11.

**TABLE 11 Effect of PEGylation of l-Asparaginase on in Vivo Half-lives in Experimental Animal Models**

| | Half-Life (h) | |
|---|---|---|
| Animal Model | Native Enzyme | PEGylated Enzyme |
| Rats | 2.9 | 5.6 |
| Mice | 3.35 | 32.9 |
| Rabbits | 20 | 144 |

### 12.4 PEG–Calcitonin

Calcitonin is a hypocalcemic hormone that lowers calcium and phosphate concentrations in patients with hypercalcemia. This effect results from decreased bone resorption and is greater in patients in whom bone turnover rates are high. Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget's disease, and in patients with osteoporosis [181]. Calcitonin is PEGylated in order to improve its enzymatic stability, in vivo hypocalcemic efficacy, and pharmacokinetics. The PEGylation is carried out by adding PEG and calcitonin to 50 m*M* phosphate buffer solution (pH 7.5) [189]. The mixture is gently shaken at room temperature for 30 min, and the reaction is quenched by adjusting the pH to around 4.0 with phosphoric acid. Youn et al. [189] examined the PEGylated enzyme for its stability in various intestinal enzymes, namely, the isolated pancreatic peptidases trypsin and chymotrypsin, the isolated brush-border peptidases leucine aminopeptidase and dipeptidyl peptidase IV, and rat intestinal homogenate. The authors observed significantly increased resistance to all intestinal enzymes applied in case of PEG–calcitonin. The degradation half-lives of PEG–calcitonin were 4.5, 2.9, and 3.1 times greater than those of free cacitonin in trypsin, chymotrypsin, and rat intestine homogenate solutions, respectively. Thus, the problem of poor systemic bioavailability of enzyme on being orally administered due to high susceptibility of enzyme to intestinal enzymatic attack was solved using a PEGylated approach. The authors further observed that liver and kidney accumulations of PEG–calcitonin at 15 and 30 min after subcutaneous injection were significantly lower than those of calcitonin by about fourfold and twofold, respectively. This, in turn, lowers the possibility of the enzyme being exposed to metabolic enzymes of liver and kidney and thus prolongs the half-life of the enzyme. Furthermore, site-specific PEGylation can preserve peptide bioactivity and maximize in vivo therapeutic efficacy. It was observed that at calcitonin equivalent doses of 100 and 200 IU/kg, total calcium decreases ($D$%) induced by PEG–calcitonin were 5.8 and 3.0 times greater than those of unmodified calcitonin, respectively. In particular, at the higher dose of

200 IU/kg, calcium levels after the intestinal administration of PEG–calcitonin decreased continuously and reached a maximum of 52% at 360 min. In contrast, unmodified calcitonin showed a maximum concentration of only 76% in plasma at 120 min [189]. Having viewed the numerous advantages of PEGylated calcitonin, Youn et al. [190] developed a method of producing a higher yield of the PEGylated product. The procedure involved conjugation of 9-fluorenylmethoxycarbonyl–calcitonin (FMOC-sCT) with PEG, and then deprotection of FMOC groups from the PEGylated FMOC-sCT. This unique site-specific PEGylation method for calcitonin using an FMOC protection/deprotection strategy produced only target isomer of PEG–calcitonin without any amino acid change in the protein, with a markedly increased production yield (86%). The findings suggested that PEGylation using FMOC-protected peptides have great potential for the mass production of site specifically PEGylated peptides with promising pharmaceutical properties [190].

## 12.5 PEG–Catalase

Catalase is a well-conserved enzyme that detoxifies hydrogen peroxide into water and oxygen [191]. The enzyme is among the most efficient known, with rates approaching 200,000 catalytic events/second/subunit (near the diffusion-controlled limit). However, the enzyme needs to be delivered to sites where the level of hydrogen peroxide increases near metastasizing tumor cells in order to achieve catalase-based inhibition/prevention of tumor metastasis. PEGylation of the enzyme was preformed with a view to prolong its retention in the blood circulation after intravenous injection [191]. This increase in blood circulation time was attributed to the altered physicochemical properties of the enzyme upon PEGylation (Table 12). The relatively higher molecular weight of PEGylated catalase made it inaccessible for the renal metabolizing enzymes, thus increasing its plasma half life, which in turn compensated for the lower enzymatic activity.

To demonstrate the antitumor activity of PEG–catalase, the authors developed clones of colon26 cells and mouse melanoma B16-BL6 cells by transfecting the firefly luciferase gene to obtain colon26/Luc and B16-BL6/Luc cells, respectively. Administration of PEG–catalase just before tumor inoculation reduced the number of B16-BL6/Luc cells in the lung 24 h after tumor inoculation. Therefore, it was concluded that PEG–catalase inhibited the adhesion of tumor cells to the endothelium in the early steps of metastasis. As a result, the ability of PEGylated catalase to inhibit pulmonary metastasis was greatly improved vis-à-vis the parent enzyme. Furthermore, the daily injection of PEG–catalase after tumor inoculation significantly increased the survival rate [191].

**TABLE 12 Physicochemical Characteristics of Catalase and PEG–Catalase**

| Physicochemical Property | Catalase | PEG–Catalase |
|---|---|---|
| Number of amino groups (modified)[a] | 112 | 26 (86) |
| Apparent molecular weight[b] | 235,000 | 665,500 |
| Enzymatic activity (%)[c] | 100 | 96.2 |
| AUC (0–24 h)[d] | 16.2 | 817.5 |

[a]The number of amino groups was determined using trinitrobenzene sulfonic acid with glycine as a standard.
[b]The apparent molecular weight was estimated by HPLC using a G4000SWXL column with the calibration curve obtained using marker proteins.
[c]The enzymatic activity was measured by monitoring the ability to degrade hydrogen peroxide.
[d]The area under the plasma concentration–time curve (AUC) up to 24 h was calculated by fitting a monoexponential equation to the experimental data of the plasma concentration of radioactivity after injection of $^{111}$In–catalase or $^{111}$In–PEG–catalase.

## 12.6 PEG–Chitosan

Chitosan, a polysaccharide derived by partial deacetylation of chitin, is widely used in pharmaceutical and medical areas, due to its favorable biological properties such as biodegradability, biocompatibility, low toxicity, hemostatic, bacteriostatic, fungistatic, anticarcinogen, and anticholesteremic properties [192, 193]. Despite these merits, the use of chitosan in formulation development is somewhat compromised due to its low water solubility [194]. Chan et al. [195] exploited PEGylation to find out the solution to this problem. To achieve this, chitosan was dissolved in acetic acid solution with gradual addition of sodium hydroxide. PEG was then added to the solution, and the reaction was conducted for 24 h at room temperature. The synthesized product was dialyzed against de-ionized water using dialysis tubing. As chitosan is widely used as a vector for gene delivery, the effect of PEGylation on the DNA binding capacity of chitosan was a major concern for the authors. So, the authors induced PEG–chitosan complexes to self-assemble by incubating DNA with the polymer. First, DNA and various amounts of chitosan or its derivative were diluted separately in 0.2 *M* sodium acetate/acetic acid buffer (pH 5.6), and an appropriate amount of polymer solution was then added to the solution of plasmid, and the resulting solution was mixed by vortex and left for 20 min at room temperature. The ability of both PEG–chitosan and chitosan to form complexes with DNA was confirmed by gel retardation assay. The

authors reported that PEGylation did not cause any alteration in the DNA binding capacity of chitosan. In addition, the presence of PEG did not add any significant cytotoxicity to chitosan, which was confirmed by estimating the relative viability of the complex in HEK 293 cells using Alamar blue assay. The fluorescence was recorded on a microplate reader with excitation wavelength at 530 nm and emission wavelength at 590 nm. Besides improving the aqueous solubility of chitosan, PEG coating around the chitosan nanocarrier systems improved their stability in the biological fluids. Consequently, the transport of bioactive macromolecules across the intestinal and nasal epithelia was facilitated [196]. The authors prepared the nanoemulsions by adding an organic phase, composed of 125 μL of miglyol, 40 mg of lecithin dissolved in 10 mL of acetone, to an aqueous phase containing Poloxamer 188 (0.25% w/v). Then, the solvents were evaporated under vacuum. Finally, 4 mL of the nanoemulsion was incubated for 1 h with 1 mL of chitosan–PEG aqueous solution (0.5% w/v) with different PEGylation degrees of chitosan (0.5 and 1%), leading to the formation of chitosan–PEG 0.5% and chitosan–PEG 1% nanocapsules, respectively. Fifty microliters of an aqueous solution of salmon calcitonin were added to the organic phase containing the oil and phospholipids. As it is well known that nanocarriers are susceptible to aggregation in media with high ionic strength, extreme pH or high enzyme/protein content, the authors investigated the effect of PEG at improving the stability of the nanoemulsions and chitosan nanocapsules in the gastrointestinal fluids. It was observed that the presence of PEG, chitosan, or chitosan–PEG attached to the oily core was found to improve the stability of the nanoemulsion, which otherwise aggregated massively upon dilution in the incubation medium. Additionally, the ability of chitosan–PEG nanocapsules in promoting the absorption of salmon calcitonin and, hence improving its pharmacological response, was studied using rats. It was observed that the $AAC_{0-24\,h}$ (area above the hypocalcemic effect curve) of the serum calcium levels–time curve after oral administration of both chitosan–PEG nanocapsules, 0.5 and 1%, was significantly higher than the nanoemulsion and salmon calcitonin aqueous solution, thus confirming the pharmacological superiorty of PEGylated chitosan carriers over untreated nanocarriers [196].

## 12.7 PEG–Cholecystokinin

Cholecystokinin (CCK), a peptide hormone secreted by the endocrine cells within the duodenal and jejunal mucosa in the gastrointestinal tract, is known to induce meal termination, delay gastric emptying, and induce satiety behavior [181]. It is widely employed for the treatment of anxiety, diarrhea, inflammatory bowel disease, and sometimes to reduce pain. However, the extremely rapid inactivation of the peptide in circulation severely hampers the unraveling of its working mechanisms. Therefore, PEGylation of CCK remains a viable and successful option to overcome this problem. The main modifications exerted by PEGylation include steric hindrance, changes in conformation, changes in electrostatic binding properties resulting in an increase in polypeptide molecular size, the reduction of its renal ultrafiltration, and the shielding of its surface from the approach of proteolytic enzymes, antibodies, or antigen-processing cells. Leon-Tamariz et al. [7] achieved PEGylation by dissolving CCK in phosphate or borate buffer and adding PEG in 1:1 or 2:1 ratio. The reaction was allowed to proceed either at 4 or 20°C under constant $N_2$ flow, and the solvents were eliminated after the completion of reaction by lyophilization [7]. The PEGylated product showed remarkable stability toward enzymatic degradation, which was evaluated by incubated CCK and PEGylated CCK in 1 mL of fresh rat plasma at 37°C. Aliquots of 20 mL were sampled every 20 s for CCK-9 and every 30 min for the conjugates. CCK-9 incubated in fresh rat plasma at 37°C showed a half-life of 2–3 min. On the other hand, HPLC chromatograms obtained from PEG–CCK conjugates, incubated under the same conditions, did not show any significant change during a 24-h period. Apart from being more stable, PEGylated CCK showed prolongation of anorectic activity too. Using rats as the animal model, the authors showed that the cumulative food intake reduction (a measure of anorectic activity), which is 1–2 h in case of nonmodified CCK, could be extended up to 6–23 h, depending upon the grade of PEG employed for PEGylation of CCK [7].

## 12.8 PEG–Antigen-Binding Fragments

Antigen-binding fragments (Fab) of antibodies can be used as therapeutics due to their monovalent antigen binding, lack of innate effector functions, and ability to be produced in a range of large-scale expression hosts such as *E. coli*. However, due to rapid renal filtration and lack of receptor-mediated recycling, Fab fragments have a very short circulating half-life in mammals. Humphreys et al. [197] applied PEGylation approach to overcome this problem. The authors di-PEGylated Fab with 20 kDa linear PEG using tris(2-carboxyethyl) phosphine (TCEP) as reductant. Reduction was carried out at room temperature for 30 min, and the product was desalted on a PD-10 desalting column (a prepacked, disposable column containing Sephadex medium for group separation of high- from low-MW substances by desalting and buffer exchange) followed by mixing with

a fivefold molar excess of PEG–maleimide over Fab. The antigen-binding capacity of Fab was not altered on PEGylation. This was confirmed by subcutaneously injecting $^{125}$I-labeled Fab–PEG and unmodified Fab in rats and analyzing the blood samples using a COBRA Autogamma counter. PEGylation conferred a serum half-life, approaching that of immunoglobulins to facilitate infrequent therapeutic dosing regimes. Apart from this, PEGylation conferred increased solubility and decreased immunogenicity, enzymatic degradation, and drug toxicity to the protein [197].

## 12.9 PEG–Glucagon

Glucagon, a 29-amino-acid single-chain peptide, is used to treat severe hypoglycemia, particularly in diabetic patients. Plasma concentrations of glucagon are elevated in poorly controlled diabetic patients. In view of its capacity to enhance gluconeogenesis and glycogenolysis, glucagon exacerbates the hyperglycemia of diabetes [181]. However, glucagon forms fibrils in aqueous solution and this property limits its therapeutic use. In a study carried out by Stignases et al. [198] glucagon was PEGylated by dissolving it in sodium hydroxide and *N*,*N*-dimethylformamide followed by addition of PEG predissolved in borate buffer [199]. The PEGylated product showed significant resistance toward fibrillation compared to glucagon. The fibrillation of glucagon and glucagon–PEG was examined using the Thioflavin T assay, a probe that interacts rapidly with amyloid fibrils inducing a strong characteristic fluorescence [199]. Apart from this, PEGylation provided conformational stability to the protein. Native glucagon has a very flexible secondary structure, which varies with the peptide concentration and solvent to give three different conformational states. In dilute aqueous solution (less than 1 mg/mL) glucagon is in a random coil with reported α-helix content of 10–15%. Structural changes can easily occur because of the low physical stability in solution of glucagon, leading to intermolecular β-sheet structure. Freeze-drying of glucagon is also known to result in an amorphous structure, which is less ordered and less crystalline-like, resulting in formation of intermolecular β sheets. Using Fourier Transform Infrared (FTIR) and circular dichroism (CD) spectroscopy as diagnostic tools, the authors remarked that PEGylation protects the internal structure of glucagon from being converted into β sheets. The authors concluded that PEGylation can be considered as a viable option to improve the stability of glucagon [199].

## 12.10 PEG–Hemoglobin

Cell-free hemoglobin (Hb) derivatives are currently being developed as promising tools for a wide range of applications, including their use as artificial oxygen carrier instead of allogenic transfusion and as oxygen transporting tools for oxygen therapeutics [200]. PEGylation of Hb is performed with a major objective of avoiding extravasation (*to force the flow of blood or lymph from a vessel out into surrounding tissue*) and to prolong the circulatory half-life of Hb. Asanuma et al. PEGylated Hb by adding activated ester of PEG-bis(succinimidyl succinate) (2.5 m*M*) very slowly to pyridoxalated Hb with stirring. To examine whether PEG–Hb increased coronary blood flow in ischemic canine heart, the authors infused PEG–Hb (10 mg/kg/min, Hb 10% solution, $n = 7$) into the coronary vein of dogs along with untreated Hb to serve as a control. It was observed that myocardial oxygen consumption in the group undergoing treatment with PEGylated Hb increased significantly vis-à-vis a control group, thus indicating that the coronary blood flow had increased [200].

In another study carried out by Li et al. [201], a new protocol, namely thiolation-mediated maleimide-chemistry-based PEGylation (extension arm facilitated PEGylation) was developed. In this process, 0.5 m*M* Hb in PBS, pH 7.4, was incubated with 5 m*M* 2-iminothilane and 10 m*M* maleimidophenyl-PEG at 4°C overnight and the reaction mixture was dialyzed extensively against PBS, pH 7.4. Purification of PEGylated Hb was carried out on a Superose 12 Prep Grade column. PEGylated Hb prepared by this method had higher oxygen affinity, a desired property for an oxygen carrier [201]. Apart from Hb, red blood cells (RBCs) have also been PEGylated with a view to increase the oxygen-carrying capacity [202]. This approach is also under investigation as a tool to generate universal red blood cells for transfusion. The authors incubated RBCs (at 5% hematocrit in the incubation buffer) with 5 m*M* dithiobis (sulfosuccinimidyl propionate) at room temperature for 1 h. After washing off the excess reagent, the cells were reincubated with 20 m*M* TCEP for 30 min in the same buffer at room temperature. The cells were washed to remove excess TCEP, incubated with 15 m*M* Mal-Phe-PEG-5000 for 2 h at room temperature, and washed again to remove excess reagents. PEGylation employing the standard blood typing test using antibodies against the respective antigens tested RBCs for blockage of the blood group antigens. Agglutination was evaluated at the macroscopic level using an agglutination viewer. It was observed that PEG chains could mask the D antigen sufficient to prevent agglutination with the respective antibodies at the microscopic level. The oxygen affinity of the PEGylated cells was measured to determine the influence of PEGylation on this property of RBCs. The authors reported significant increase in oxygen-carrying capacity of RBC on being PEGylated [202].

### 12.11 PEG–Histaminase

Diamine oxidases, originally referred as histaminases, are homodimeric copper amine oxidases which catalyze the oxidative deamination of several primary biogenic amines. For this reason, histaminases present good perspectives for therapeutic applications in myocardial ischemia treatment [203]. The major objective of PEGylation of histaminases is to reduce the high degree of immunogenicity associated with histaminase treatment and prolongation of plasma half life. Federico et al. [203] prepared PEGylated histaminase by adding linear PEG activated as $pNO_2$ phenyl formate at room temperature in small portions and under rapid stirring to diamine oxidase (0.5 mg/mL) dissolved in 0.1 *M* phosphate buffer, pH 8.5. The conjugation reaction was carried out for 4 h, while the pH was maintained with 0.05 *M* NaOH. In order to evaluate the immunological properties of either native or modified histaminase, the ability to elicit antihistaminase IgG or IgM immune response after mouse boosting with native histaminase, PEG histaminase, was measured. The authors reported that PEG derivatives elicited a slower immune response and the maximal IgM concentration reached after the fifth immunization was about 50–80% lower, when compared with the native protein. The pharmacokinetic behavior of native and PEGylated histaminase was evaluated by determining the enzymatic activity in serum after single intravenous administration to mice. It was observed that plasma half-life of PEGylated product increased and its clearance decreased vis-à-vis the native enzyme [203].

### 12.12 PEG–Horseradish Peroxidase

Horseradish peroxidase (HRP) is a versatile enzyme that finds applications in chemical, environmental, pharmaceutical, and biotechnological industries [204]. However, the nonrecovery of the enzyme in certain reactions is a retarding step in its development, which has been sorted out by PEGylation technology. A two-step process was adopted for the conjugation of PEG to HRP. First, PEG was activated with *p*-nitrophenyl chloroformate and then the activated PEG was mixed with HRP in molar ratios ranging from 1:10 to 1:500. The PEG–HRP conjugates were apparently more tolerant toward organic inactivation than the native HRP. Jeng et al. [204] reported that while the PEG–HRP conjugates exhibited 70% residual activity at acetonitrile concentrations up to at least 70%, the residual activity of native HRP droped significantly at acetonitrile concentrations above 40%. The authors further examined the capability of PEGylated HRP to catalyze the polymerization of 2-napthol. Fifteen micrograms of PEG–HRP were added to 2-napthol and dissolved in aqueous buffer (at a concentration of 0.15 *M*) containing the designated amount of acetonitrile. The authors observed that the yield of product increased significantly using PEGylated enzyme instead of native enzyme. Apart from this, the PEGylation approach allowed successful recovery of the enzyme at the end of reaction, so that it could be used in other reactions [204].

### 12.13 PEG–Glucagon-like Peptide

Glucagon-like peptide-1 (GLP-1) is a proglucagon-derived hormone secreted from enteroendocrine L cells of the intestine in response to oral ingestion which stimulates insulin secretion and inhibits glucagon secretion in a glucose-dependent manner [205]. The biological half-life of GLP-1 in plasma is only a few minutes (~2 min) due to severe proteolytic attack on being released into circulation. PEGylation can increase the therapeutic potential of PEG–glucagon-like peptide by enhancing the proteolytic resistance, diminishing glomerular filtration, thereby prolonging the biological life-time. Youn et al. [205] performed PEGylation of GLP by adding aldehyde derivative of PEG to GLP (2 mg/mL) in a 50-m*M* acetate buffer solution (pH 5.5) containing 20 m*M* sodium cyanoborohydride (molar ratio of GLP-1 to PEG = 1:2). The reaction was allowed to continue at 4°C for 2 h and was quenched by adjusting the pH to ~2.2 with 1% deionized water. The authors assessed insulinotropic activities of GLP-1 and PEGylated GLP-1 using isolated rat pancreatic islets. Twenty islets were incubated for 2 h in 2 mL of Krebs ringer bicarbonate (KRB) buffer at 37°C. The concentration of insulin released was determined using an enzyme immunoassay (EIA) kit. The results of these experiments revealed that insulinotropic activity of GLP was well preserved on being PEGylated. It was also observed that PEGylation protected the peptide from proteolytic attack. The shielding of metabolic sites due to increased streric hindrance is the underlying mechanism by which PEG protects GLP-1 from proteolytic attack. Thus it can be concluded that PEGylated GLP can be used as a viable option for treating type II diabetes due to the well-preserved insulinotropic activity, the increased proteolytic stability, and thereby the improved glucose-stabilizing capability [205].

### 12.14 PEG Islets

Insulin-dependent diabetes mellitus (IDDM) or type I diabetes mellitus is a severe form associated with ketosis in the untreated state. It occurs most commonly in the juveniles but occasionally in adults [206, 207]. Itis a catabolic disorder in which circulating insulin is

virtually absent, plasma glucagon is elevated, and the pancreatic β cells fail to respond to all insulinogenic stimuli. Exogenous insulin is required to reverse the catabolic state, prevent ketosis, and reduce hyperglucagonemia and elevated blood glucose levels [206]. One of the widely used methods, if exogenous insulin is not successful, to treat type I diabetes mellitus is pancreatic islet transplantation [208]. This treatment is based on the hypothesis that the transplanted islets would start secreting insulin and also trigger other islets to secrete it. But the greatest risk faced during any type of transplant is autoimmune rejection. In case of islets transplantation, PEGylation technology has emerged out as a viable option to combat immune response. In a process described by Lee et al. [209], the islets were first washed with Hank's balanced salt solution (HBSS) and then incubated in the HBSS (pH 8.0) containing 0.25% w/v active PEG–succinimidyl propionic acid for 1 h. Finally, the PEGylated islets were washed twice and cultured in the culture medium for one more day. In order to examine whether PEGylation reduces immunorejection of islets, the authors devised a unique procedure. A capsulotomy was performed on the caudal outer surface of the left kidney of diabetic rats and unmodified islets or PEGylated islets were injected (1200 islets/recipient). The tail vein blood glucose level of these rats, which were kept under free feeding condition, was measured daily with a portable glucometer for 100 days. Transplantation was considered successful if the blood glucose level returned to normal (<120 mg/dL) and remained normal for the first 2 days after islet transplantation. Islet rejection was diagnosed when the blood glucose level became hyperglycemic (blood glucose >200 mg/dL) for 2 consecutive days. The authors also examined whether there was any dose reducing effect of PEGylation of islets on the dose of immunosuppressant agent, cyclosporine A. It was observed that unmodified islets in all the recipients were completely rejected within 2 weeks, although cyclosporine A was continuously administered for up to 2 weeks. On the other hand, 3 out of 7 recipients of PEGylated islets survived for 100 days although cyclosporine A treatment was stopped after 2 weeks [209].

### 12.15 PEG–Lysozyme

Lysozyme (1,4-β-*N*-acetylmuramidase) is an enzyme that plays an important role in the prevention of bacterial infections. It acts by attacking a specific component of certain bacterial cell walls, peptidoglycan. Peptidoglycan is composed of the repeating amino sugars, *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM), crosslinked by peptide bridges. Lysozyme acts by hydrolyzing the bond between NAG and NAM, increasing the bacteria's permeability and causing the bacteria to burst [210]. The biggest challenge in formulation development of proteins and peptides is their tendency to aggregate. Surface-induced clustering can lead to the generation of a pool of aggregated and inactive protein. Consequently, these aggregated molecules lead to a more severe immune response. However, covalent grafting of proteins to PEG can reduce their aggregation tendencies. Lysozyme has been successfully PEGylated with a view to stabilize its formulation. Daly et al. [211] examined the effect of PEGylation on tendency of lysozyme to self-aggregate. The authors passed a mixture of di-PEGylated lysozyme along with thioflavin T through the TIRF (total internal reflection flourescence) cell which is used to study the self aggregation behavior of peptides. The authors observed that di-PEGylation of lysozyme decreased the number of protein–protein contacts in an adsorbed layer. Thus, it can be stated that PEG grafting might improve the functional stability of therapeutic proteins during manufacture, storage, anddelivery by reducing surface-induced aggregation [212].

### 12.16 PEG–Phenylalanine Ammonia-lyase

Phenylalanine ammonia-lyase (PAL) is an enzyme used for first-line treatment of phenylketonuria, a metabolic disorder that results from impaired activity of hepatic phenylalanine hydroxylase. This enzyme is responsible for the metabolism of the majority of phenylalanine intake [213]. Patients with phenylketonuria display impaired neurophysiological functioning and reduced cognitive development. Gamez et al. PEGylated PAL by coupling linear 20-kDa methoxy-PEG-SPA to PAL. The authors proposed that the uniform coverage of the protein by PEG will help to mitigate an immune response. The identified immunogenic regions of PAL can be covered through a process of site-specific mutagenesis to introduce additional lysine residues followed by PEGylation [213]. Besides reduced immunogenicity, PEGylated PAL possesses better specific activity and prolonged half-life [214].

### 12.17 PEG–Lysine

Lysine is an essential amino acid important for proper growth, and it plays an essential role in the production of carnitine, a nutrient responsible for converting fatty acids into energy and helping to lower cholesterol [181]. Lysine appears to help the body absorb and conserve calcium, and it plays an important role in the formation of collagen, a substance important for bones and connective tissues including skin, tendon, and cartilage.

**Figure 16** Structure of dendritic poly (L-lysine) [31].

Pharmacologically, lysine is used to treat herpes, shingles, osteoporosis, and mild inflammation [181]. PEGylation has been widely employed to modify proteinaceous pharmaceuticals to reduce toxicity and immunogenicity and increase water solubility, stability, and plasma half-life. Nowadays, a variety of small and narrow sized drug carriers are utilized to deliver drugs to small sized tumors. One such carrier gaining widespread attention is lysine dendrimer (Fig. 16). Since lysine dendrimers have many reactive primary amino groups, they can be modified by several functional groups. One such modification is PEGylation, aimed at achieving sustained blood levels of drugs after intravenous administration. Okuda et al. [31] PEGylated the lysine dendrimers by dissolving them in borate buffer (pH 9.8) and reacting with PEG at 4°C. After an overnight incubation, the reaction mixture was ultrafiltrated and the purified PEGylated lysine dendrimer was then lyophilized. The authors employed mice as experimental animals to study the plasma residence time and biodistribution of PEGylated lysine dendrimers. It was reported that while the intact lysine was rapidly eliminated from the circulation within a few minutes, the retention of PEGylated lysine derivatives was enhanced by modification with PEG chains up to 1 h. The biodistribution characteristics of PEGylated lysine derivatives and intact lysine were evaluated until 60 min postintravenous injection into mice by measuring the radioactivity in the organs and urine. It was observed that there was no accumulation of PEGylated lysine in liver or kidney, thus confirming their presence in blood circulation. To further investigate whether the PEGylated lysine shows tumor tissue accumulativeness, PEG–lysine, which showed a better blood etention, was radiolabeled and was subjected to tumor-bearing mice. Although the intact lysine hardly showed tumor accumulativeness, PEG–lysine gradually and effectively accumulated in tumor tissue [31].

## 12.18 PEG–Fibroblast Growth Factor

Human acid fibroblast growth factor (rhaFGF) is a mitogenic cytokine that can stimulate mesoderm- and neuroectoderm-originated cell proliferation. However, the widespread use of haFGF is restricted by short half life and high immunogenic activity. Huang et al. [215] PEGylated rhaFGF by incubating it with 30-fold molar excess of 5-kDa PEG–maleimide in PBS at 25°C for 4 h to allow efficient reaction. The reaction mixtures were directly loaded on a Sephadex G-25 column to eliminate the free salts. The desalted PEG–rhaFGF conjugate was loaded on a CM-Sepharose column previously equilibrated with 20 m*M* phosphate buffer (pH 7.0), and eluted with buffer B (0.6 mol/L NaCl in 20 mmol/L PB, pH = 7.2). To assess the biostability of the PEGylated product, the authors incubated PEGylated rhaFGF with mouse serum under different temperatures. It was reported that compared to the native rhaFGF, PEGylated rhaFGF was resistant to incubation-decreased cell proliferating action. To assess the immunogenicity of PEGylated rhaFGF, BALB/c mice were given, by intraperitoneal (ip) injection of rhaFGF at a dose of 1.9 μmol/mouse in 50 mmol/L PBS. The PEGylated product elicited only a mild immune response compared to native peptide which was due to decreased uptake of PEGylated protein by antigen-presenting cells in vivo. Another important finding of the present study was to physiologically confirm that PEGylated rhaFGF provided a more effective protection than native rhaFGF, against infrared (IR)-induced retinal damage in the animal model. Using a rat model, PEGylated rhaFGF showed a better protection than native rhaFGF against I/R-induced retina damage, examined not only by morphological observations but also by biochemical measurement of lipid peroxidation [215].

## 12.19 PEGylated–Granulocyte-Macrophage–Colony-Stimulatinng Factor (PEG–GM–CSF)

GM–CSF belongs to a family of colony-stimulating factors that regulate proliferation and differentiation of hematopoietic cells. Recently, GM–CSF has shown promising results in treatment of Crohn's disease, a severe chronic inflammatory gastrointestinal disorder. Lysine-directed PEGylation-modified GM–CSF to address its limited half-life and rapid renal clearance. Sainathan et al. [216] performed the amine-directed PEGylation of mGM–CSF using mPEG–succinimidyl propionate MW 5000 (mPEG–SPA) [216]. GM–CSF was derivatized using a 5 : 1 molar excess of mPEG–SPA in PBS at pH 8.2 for 30 min at 25°C. To study the half-life of recombinant PEGylated GM–CSF, mice were injected intraperitoneally with a single dose (5 μg) of unmodified

recombinant GM–CSF or PEGylated GM–CSF. Blood was collected at different time points and serum GM–CSF concentration was estimated using an ELISA kit. Unmodified GM–CSF was rapidly cleared ($t_{1/2}$: 2–6 h). Animals treated with PEGylated GM–CSF had similar peak levels and a prolonged $t_{1/2}$ (>48 h) [216].

### 12.20 PEGylated–Granulocyte–Colony-Stimulating Factor (PEG–G–CSF)

G–CSF is a growth factor useful in the reatment of cancer-induced nutropenia. It is commercially synthesized in *E. coli* as recombinant methionyl human granulocyte-colony stimulating factor (r-metHuG–CSF), which is also known as Filgrastim marketed as NEUPOGEN by Amgen Inc. [217]. It is a 175-residue protein folded into a 4 helical bundle containing one cysteine residue at C17 and two disulfide bonds that stabilize the molecule at low pH. Filgrastime has a short median serum half-life of 3.5–3.8 h that lead to the development of pegfilgrastim or PEGylated r-metHuG–CSF (NEULASTA) [218]. Pegfilgrastim is an improved version of filgrastim with longer half-life, increased physical stability, higher solubility, and reduced dosing frequency. It has better patient acceptability as only one sc injection is required per chemotherapy schedule compared to the daily dosing of filgrastim. As Pegfilgrastim is a large molecule formed by covalent conjugation of 20 kDa PEG to α-amino group of N-terminal methionine group of filgrastim, it has poor renal clearance and, thus, increased mean plasma residence time [53].

### 12.21 PEG–SN38 (EZN-2208)

As a carrier, PEG has poor drug-loading property due to the presence of only two reactive groups in each polymer chain, which could be improved by imparting a dendrimer-like formation to the PEG end chain [219]. Enzon Pharmaceuticals is working on a similar strategy, where SN-38, a CPT (camptothecin) metabolite is conjugated to a four-armed 40-kDa PEG forming EZN-2208. Phase I clinical trials of iv EZN-2208 are being carried out on patients with advanced solid tumors.

### 12.22 PEGylated–Cyanovirin-N (PEG-CV-N)

CV-N is a potent virucidal bacterial protein isolated from the cyanobacterium *Nostoc ellipsosporum*. It is an entry inhibitor of HIV and permanently inactivates various clinical isolates and laboratory strains of HIV-1, HIV-2, SIV (simian immunodeficiency virus), FIV (feline immunodeficiency virus), herpes virus-6, hepatitis-C virus, influenza virus, and Ebola virus [220]. As CV-N is a bacterial protein, it presents various unwanted effects such as immunological reactions, rapid renal clearance, and inflammation of mucous membrane [221]. Thus, to overcome these unwanted effects, PEGylation was employed as the method of choice. Site-directed mutagenesis of CV-N and various mutants were tested. A mutant in which amino acid residue replacement did not interfere with its high carbohydrate binding capacity was selected [CV-N(Q62C)] for PEGylation [222]. Molecular cloning, protein expression, and purification of CV-N were performed. Purified CV-N(Q62C) was PEGylated with 20 or 30 kDa mPEG–maleimide at pH 7.2. SDS–PAGE and SEC (size exclusion chromatography) methods were used to carry out qualitative analysis and separation of PEGylated and free CV-N(Q62C). The yield, purity, and molecular weight of eluted PEG conjugates were determined by reversed-phase HPLC, gel permeation HPLC, and MALDI-TOF mass spectrometry, respectively [223]. The result of an in vitro anti-HIV assay showed that the mutant selected for PEGylation (Q62C) displayed reasonable activity and maintained efficacy equivalent to that of AZT (azidothymidine). An ELISA-type endpoint titer assay determined that immunogenicity of PEGylated–CV-N was lower then non-PEGylated form of the protein [224].

### 12.23 PEG–Methioninase (PEG–METase)

Methioninase (methionine-α-deamino-γ-mercaptomethane-lyase; METase) is a homotetramer pyridoxal-L-phosphate-dependent enzyme composed of 398 amino acids and isolated from *Psudomonas putida*. It is a low toxic enzyme with anticancer properties [225]. However, METase is immunogenic in nature and has a short half-life of 80–120 min on iv injection into the body. PEGylation of METase with succinimidylpropionate or succinimidylglutarate activated 5000 Da methoxy-PEG reduced its immunogenicity [226]. PEGylation also increased its half-life (12–30 h) and duration of methionine depletion in serum (24–72 h) depending upon PEG–methioninase molar ratios.

### 12.24 PEG–Arginine Deiminase (PEG–ADI)

Arginine deiminase (ADI) is an enzyme that degrades arginine into citrulline and ammonia. Some cancer cells cannot synthesize arginine and its depletion causes cell apoptosis [225]. Thus, arginine-depleting enzymes such as ADI are useful agents for killing arginine-auxotrophic cancer cells [227]. However, continuous low enzyme levels are required for extended periods to ensure cancer cell death, whereas ADI has high immunogenic-

ity and short serum half-life (5 h). PEGylation of recombinant ADI with PEG chain of 12,000 or 20,000 Da activated as succinimidyl carbonate decreased the immunogenicity and increased the plasma mean residence time of the enzyme up to 30-fold in mice [225]. A single iv dose of PEG–ADI (either 12,000 or 20,000 Da) reduced plasma levels of arginine below detectable limits within 1 h of administration and maintained the same for 10 days.

# GOLD STANDARD ANIMAL MODELS

Carol Castaneda and Michael S. LaPointe
*Indiana University Northwest, Gary, Indiana*

## 1 INTRODUCTION: IMPORTANCE OF AND DANGERS IN USING ANIMAL MODELS FOR DRUG DEVELOPMENT

Using data from animal models for designing and approving human trials is necessary but must be done cautiously. Animal models should be characterized carefully and compared to similar human systems including in vitro studies using human cells. For example, CD4 is expressed on human macrophages but not on murine macrophages. Using multiple animal models is important and no data from any of these systems should be ignored. When animal models are used to examine the efficacy of treatment, it is very important that treatment in animal models start after clinical symptoms become evident. Moreover, drugs should also be tested using in vitro human systems when available. Well-characterized animal models can also be used to examine the ability of certain prophylactic treatments to prevent the onset of disease or pathologic symptoms. Finally, human trials should be based on sound scientific evidence using animal models and other appropriate model systems. Even when human trials go awry, we must investigate the results openly and carefully in order to determine why there were differences between the human trials and the animal models. This will lead to the development of better models and thus faster and more effective treatments in the future.

Testing of biologics has dramatically expanded the horizon of possible treatments; a successful example being infliximab, a tumor necrosis factor-alpha (TNF-α) inhibitor used to treat rheumatoid arthritis. Caution must be taken when using antibody reagents. These reagents may be fully or partial agonistic or antagonistic, leading to very different treatment results. Often these antibodies are thought to block or activate the function of cytokines or specific cellular receptors. It is important, therefore, to rigorously test the effects of these reagents in several animal models due to the complex intricacy and redundancy of all living systems and therefore the many possible dangers.

Monoclonal antibody reagents have often been used to block a specific signaling receptor. However, it has been shown in animal models that a monoclonal antibody (mAb) can cross-link the receptor it binds and thus result in signaling rather than blocking the signal [1, 2]. This cross-linking is especially powerful if the fragment crystallizable (Fc) region of the treatment antibody binds to Fc receptors on the patient's own cells, resulting in extensive cross-linking. Complement activation and other inflammatory responses are, therefore, very real possibilities as a result of monoclonal antibody treatment. Although there are dangers in using these treatments, there is also the exciting potential in transplantation, cancer, and autoimmune disease. Some evidence suggests that short-term treatment with the antibodies that block T-cell activation may result in long-term autoantigen-specific tolerance and remission from clinical disease.

## 2 IMMUNOMODULATION

For activation, T lymphocytes require antigen-specific signals through the binding of their T-cell receptor (TCR) complex and co-stimulatory signals including

**Figure 1** For activation, T lymphocytes require antigen-specific signals through the binding of their T cell receptor (TCR) complex and costimulatory signals including signals through their CD28. CD28 on the T cell binds CD80 and CD86 on an antigen-presenting cell (APC).

**Figure 2** CD80 and CD86 on the APC also bind CTLA-4 on activated T cells. Binding of CTLA-4 transduces a negative signal, causing the activated T cell to stop proliferating.

signals through their CD28 and CD154 receptors. CD28 on the T cell binds CD80 (B7-1) and CD86 (B7-2) on an antigen-presenting cell (APC). In fact, binding of the antigen-specific TCR alone actively induces anergy (T-cell unresponsiveness), leaving these T cells unable to respond even to an APC expressing co-stimulatory receptors (Fig. 1). CD80 and CD86 can also bind to a negative regulator of T-cell proliferation, CTLA-4 (CD152), found in higher concentration on activated lymphocytes (Fig. 2). CD154 on T lymphocytes binds CD40 on dendritic cells (APCs) and on B lymphocytes (Fig. 3). This interaction is necessary for the activation of B cells and maturation of dendritic cells. Antibodies designed to bind any of these receptors can modulate the immune response and can be antagonists, partial agonists, or agonists.

Once T lymphocytes are activated, these effector cells must travel to and enter the area of infection/inflammation. Receptors such as very late antigen (VLA)-4 on activated T cells are required for entrance into the inflamed tissue and are therefore targets for blocking mAb therapy. Activated T lymphocytes can be

**Figure 3** CD40/CD154 interaction signals activation/maturation for dendritic (APCs), T helper cells and B lymphocytes.

functionally diverse, including $CD4^+$ helper T cells (type 1, type 2, or type 17), $CD8^+$ cytotoxic lymphocytes, or $CD4^+CD25^+$ regulatory T cells, which can be powerfully immunosuppressive.

Using two mouse models of the human demyelinating disease multiple sclerosis (MS), Remitting experimental autoimmune encephalomyelitis (R-EAE) and Theiler's murine encephalomyelitis virus-induced demyelinating disease (TMEV-IDD), along with the NOD mouse model of type I diabetes, we will demonstrate the importance of understanding the structure and function of the drug being tested and the pathology in the animal models being used.

## 3 RELAPSING REMITTING EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Relapsing remitting experimental autoimmune encephalomyelitis (R-EAE) in SJL mice is an artificial but useful animal model of the human demyelinating disease multiple sclerosis. Myelin is the lipid insulation found on many nerve axons. The presence of myelin covering these axons is necessary for efficient propagation of the neuronal signal. Central nervous system (CNS) demyelinating disease is induced in genetically identical SJL mice by subcutaneous immunization with 100 μL complete Freund adjuvant emulsion containing *Mycobacterium tuberculosis* H37Ra plus a myelin antigen such as proteolipid protein (PLP) or myelin basic protein (MBP) or specific PLP or MBP peptides. Disease in these mice follows a relapsing/remitting course.

**Figure 4** Blockade of costimulation during remission in PLP 139–151-induced R-EAE effects epitope spreading.

The immune response along with the resulting clinical disease has been carefully characterized in this murine R-EAE model of MS. We are able to induce disease with a specific myelin epitope and verify that acute disease is due to T-helper type 1 lymphocytes targeting this epitope, for example, PLP 139–151. During the acute phase of disease and into remission, T cells specific to other epitopes on myelin are becoming activated (epitope spreading), probably due to interferon-gamma (IFN-γ)-induced tissue damage at the inflammatory site (Fig. 4). These newly activated autoreactive T cells are responsible for clinical relapse [3]. This animal model demonstrates the difficulty when searching for an antigen-specific treatment for human autoimmune disease since the target of the T-cell

response changes with time. Human autoimmune diseases such as MS and type I diabetes confirm this phenomenon of epitope spreading in human disease.

## 4 BLOCKADE OF T-CELL CO-STIMULATION USING ANTI-B7 MONOCLONAL ANTIBODIES IN R-EAE

Using the mouse model of MS, relapsing R-EAE in SJL mice, anti-B7-1 monoclonal antibodies were used to treat mice during remission after the acute phase of disease. The rational for this treatment was that co-stimulation blockade would anergize autoreactive T lymphocytes being activated in vivo during initial myelin damage and would therefore block relapses. Instead of blocking further relapses as was expected, this treatment resulted in exacerbation of disease relapses [1]. Further examination of the effects of whole antibody treatment demonstrated that CNS-infiltrating $CD4^+$ T-helper type 1 (TH1) lymphocytes bound anti-CD80 mAb; that increased activity and survival of these autoreactive lymphocytes correlated with exacerbation of disease; and in vitro studies demonstrated that cross-linking CD80 on these T cells with the addition of TH1 cytokines increased T-cell production of T-bet, IFN-γ, and Bcl-x [4]. These findings are interesting since T-bet is a transcription factor essential for the development of TH1 lymphocytes and the transcription of the IFN-γ gene while Bcl family members are important in down-regulation of an immune response via apoptosis of effector T cells. This data may be relevant to human MS since during disease the expression of B7-1 in the CNS is high both in this mouse model and in human MS.

Subsequent treatment under the same experimental conditions with anti B7-1 F(ab) fragments, which contain only one binding site and therefore cannot cross-link, resulted in profound and extended inhibition of disease relapses [2]. Epitope spreading results from the activation of T lymphocytes. Therefore, blocking co-stimulation during the activation of these newly recruited autoreactive T cells should stop epitope spreading. As demonstrated in R-EAE, treatment with anti-B7-1 F(ab) not only blocked clinical disease but also halted epitope spreading. The T-cell response to the spread epitopes such as PLP 178–191 was blocked (Fig. 4). This work demonstrates the importance of understanding the treatment reagent and the animal model being used.

## 5 BLOCKADE OF T-CELL CO-STIMULATION WITH CTLA4-IG (ABATACEPT AND BELATSCEPT)

CTLA4-Ig is a fusion protein that includes the B7-binding domain of CTLA-4 (abatacept) and therefore binds both B7-1 and B7-2. Treatment with CTLA4-Ig blocks both B7-1 and B7-2 interactions, in contrast to the anti-B7-1 F(ab) treatment described above. This biologic has been shown to block allograft rejection and autoimmune disease in various animal models, even resulting in long-term tolerance [5]. In SJL R-EAE, treatment with CTLA4-Ig downregulates epitope spreading and mediates remission from disease. No noticeable adverse effects were seen [6]. In human trials, abatacept treatment reduced psoriatic lesions in patients with psoriasis vulgaris and demonstrated significant improvements in the signs and symptoms of rheumatoid arthritis (RA) including long-term inhibition of structural damage. No significant detrimental side effects were seen unless RA patients received both abatacept and anti-TNF agents. Abatacept has been approved by the Food and Drug Administration (FDA) for treating rheumatoid arthritis.

Development of belatacept is an excellent example of using animal models carefully and to our advantage. Although CTLA4-Ig (abatacept) induces prolonged graft survival in rodent models of transplantation, this biologic did not prove effective in nonhuman primate models of renal transplantation. During these studies, it was recognized that abatacept binds preferentially to B7-1. In response to this knowledge, the second-generation CTLA4-Ig, belatacept, was produced. Belatacept binds more strongly to both B7s; in nonhuman primate studies belatecept demonstrated better efficacy and is showing promise in phase II human trials [5].

## 6 THEILER'S MURINE ENCEPHALOMYELITIS VIRUS–INDUCED DEMYELINATING DISEASE

Theiler's murine encephalomyelitis virus—Induced demyelinating disease (TMEV–IDD) is a virally induced demyelinating disease with clinical disease progression and CNS histopathology much like the progressive form of human MS. The virus remains chronic in the CNS of SJL mice, however, myelin damage appears to be due to a T-helper type 1 inflammatory response targeting myelin not virus-infected cells. In fact, within 30 days of infection, the target of the immune response appears to include myelin components, and specific autoreactive T lymphocytes are found in the CNS along with activated macrophages, which are stripping and engulfing myelin from the neuronal axons. Epitope spreading, as characterized in the simpler more artificial MS model R-EAE, progresses in TMEV–IDD from viral epitopes to the immunodominant epitope PLP 139–151 and finally to other epitopes on PLP, MBP, and additional myelin proteins [7].

As a mouse model of MS, TMEV–IDD is more complex than R-EAE. As one might expect, attempts to block T-cell activation and the resulting macrophage-induced demyelination can lead to increased levels of virus and do not result in significant and long-lasting inhibition of disease progression.

## 7 BLOCKADE OF CD154/CD40 SIGNALING IN R-EAE AND TMEV-IDD

A second co-stimulatory signal important to the maturation of dendritic cells, B lymphocytes, and T lymphocytes is the CD154/CD40 interaction (Fig. 3). This co-stimulatory pathway is a good example of the complex functionality of many signaling molecules and the important variation of expression in different animal models compared to the expression on human cells. CD154 is found on activated T lymphocytes in both mice and men. However, this receptor is also found in humans on activated dendritic cells, mast cells, monocytes/macrophages, neutrophils, and platelets. CD40 is expressed on mouse and human dendritic cells, monocyte/macrophage, and B lymphocytes. CD154 blockade has been used successfully to inhibit disease progression in many autoimmune animal models including R-EAE, TMEV-IDD [8] and NOD [9].

Anti-CD154 treatment in both R-EAE and TMEV-IDD resulted in reduced severity of clinical signs and CNS demyelination. Treatment of R-EAE in SJL mice with a total of four injections of blocking anti-CD154 given every other day beginning at the peak of the acute phase or during remission (Fig. 4) reduced the severity of clinical disease, the number and severity of disease relapses, and the infiltration of IFN-γ-producing T cells into the CNS. No significant adverse reactions were noted [10].

CD154 blockade using a similar protocol in TMEV-IDD resulted in a temporary reduction of disease progression along with the reduction of CNS infiltration by T cells and macrophage [11]. The temporary quality of this inhibition may be due to the chronic nature of the viral infection of the CNS. Since a previous or concurrent viral infection is hypothesized as a trigger for human MS, results of treatment in this virally induced MS model are pertinent to human trials. No adverse reactions were noted in these experiments.

Although CD154 blockade in many animal models of autoimmunity and transplantation has been successful and exposed no adverse reaction, clinical trials in human autoimmune disease were halted due to a low but significant incidence of thrombotic events—inappropriate blood clotting leading to tissue damage as in coronary thrombosis. This is no doubt connected in some way to the expression of CD154 on human platelets.

## 8 BLOCKADE OF CD154/CD40 SIGNALING IN NONOBESE DIABETIC MICE (NOD)

Anti-CD154 treatment of NOD mice demonstrates the variation in clinical outcomes dependent on the time of treatment relative to the pathology. Female NOD mice spontaneously develop inflammation of the pancreas at around 3–5 weeks of age. This insulitis is followed by diabetes due to the inflammatory destruction of the β cells of the pancreas, which produce insulin. Diabetes, defined by the increase in blood glucose, occurs between 3 and 7 months of age in the NOD mice. This model of insulin-dependent diabetes mellitus (IDDM) closely resembles human IDDM in histopathology and clinical presentation. Infiltration of the pancreas by T lymphocytes and activated macrophage set the stage for destruction of the pancreatic β cells exclusively. No other pancreatic cells are destroyed [12]. In the mouse model and in human IDDM, the epitope spreading phenomenon has been proposed and much data supports this proposal.

Treatment with anti-CD154 mAb at 3 weeks of age, prior to onset of diabetes, completely prevented insulitis and diabetes. This time-dependent efficacy can also be seen when these mice are treated with other biologics such as anti-CD3 antibody [12]. Treatment of human patients prior to clinical disease onset will present some problems. However, since IDDM tends to run in families, early treatment may be possible. Interestingly, even though T-cell involvement is unquestioned in both mouse model and human IDDM, depletion of B cells by treatment with anti-CD20 (retuximab) is in human diabetes trials and has been tested and studied in a transgenic NOD mouse model in which the human CD20 molecule is expressed on mouse B lymphocytes [13].

## 9 ANTI-CD3 (TCR) IN EAE AND NOD

Responses to drugs can be very different depending on the animal model used, nature of the biologic, dose given, and when treatment begins. The clinical outcome of treatment with antibodies against the T-cell receptor in murine and human autoimmunity differ greatly depending on the Fc portion of the antibodies used. Although Fc receptor-binding (mitogenic) anti-CD3 mAB were used to successfully treat many transplantation and autoimmunity animal models, the initial cytokine burst induced due to massive T-cell activation is a potential problem. Short-term treatment with Fc receptor nonbinding (nonmitogenic) anti-CD3 (teplizumab) in both EAE and NOD resulted in disease reversal and long-term tolerance without the initial cytokine burst [14–16].

A short, 5-day treatment protocol with nonmitogenic anti-CD3 given after the peak of the acute phase in R-EAE (Fig. 4) resulted in reversal of disease, inhibition of disease relapse, and reduction in type 1 cytokines like IFN-γ, Interleukin-12 (IL-12), and TNF-α [16]. This treatment protocol in the NOD mouse had little effect when started after clinical disease [14]. No adverse reactions were noted.

Teplizumab trials in new onset diabetic patients have been encouraging; however, improvements were seen mainly in patients with less β-cell damage at treatment onset—mirroring the outcome in the NOD animal model. Disease progression stopped in these patients for over a year after treatment and insulin requirements were reduced. Although side effects were much reduced compared to the mitogenic anti-CD3, some minor flulike side effects were experienced due to a limited cytokine release at the time of injection [14].

## 10 A SUPERAGONISTIC ANTI-CD28 MONOCLONAL ANTIBODY (VISILIZUMAB) IN LEWIS RAT EAE AND ADJUVANT ARTHRITIS ANIMAL MODEL

CD28 is expressed on all T lymphocytes (Fig. 1), including helper, cytotoxic, and regulatory T lymphocytes. In both a Lewis rat model of multiple sclerosis, experimental autoimmune encephalomyelitis [17], and in a rat model of rheumatoid arthritis, adjuvant arthritis [18], a superagonistic anti-CD28 monoclonal antibody proved to be an effective treatment. Characterization of the immune response in treated rats suggested that protection from disease was due to the activation of regulatory T lymphocytes. Activation of such regulatory T cells has been an exciting area of research, promising new ways to reduce inappropriate immune responses including autoimmunity.

It is important to note that the treatment in these animal models occurred prior to or immediately upon onset of clinical disease and treatment with this antibody apparently did not require antigen-specific TCR signals for T-cell activation. Both of these details demonstrate the need for caution. Unfortunately, a human trial of an anti-CD28 superagonist TGN1412 resulted in the hospitalization of six human volunteers [19, 20]. It became apparent that in humans this antibody treatment resulted in indiscriminant activation of helper T cells with a resulting "cytokine storm."

Understanding the biologic reagent used may be the important insight in this case. Antibodies to be used in human trials are usually bioengineered to include the human constant region in order to extend their half-life. This Fc domain is the functional end of the antibody, binding to Fc receptors on many cells in the body and inducing various responses, including secretion of inflammatory cytokines. The human Fc portion of this biologic may not bind to the Fc receptors on the cells in the animal models tested. Once introduced into humans, the unforeseen binding of the Fc portion of the antibody to the Fc receptors on the human T-helper lymphocytes and APCs probably induced the massive secretion of these potent cytokines.

## 11 T-CELL MIGRATION BLOCKADE WITH ANTI-VLA-4 (NATALIZUMAB)

Migration of encephalitogenic $CD4^+$ T cells into the CNS during the induction of R-EAE in SJL mice is dependent on the binding of VLA-4 (α4β1), expressed by the autoactivated T cell, to the endothelial cell ligand VLA-4 calcium-dependent adhesion molecule (VCAM)-1. Blockade of this migration with an anti-VLA-4 antibody, or a small-molecule VLA-4 antagonist (monovalent), prior to clinical disease, delays and inhibits disease onset. However, treatment after onset of clinical disease does not significantly inhibit disease. In fact, treatment with either VLA-4 antagonist during the first remission (Fig. 4) results in enhanced disease and in all treatment protocols, once treatment is halted, significant disease exacerbation occurs [21, 22].

Interestingly, even using protocols that inhibited disease, treatment with VLA-4 blockers enhanced proliferation and IFN-γ production by myelin-specific splenic T cells. These T cells are not only specific for the priming epitope (PLP 139–151) but also to newly spread epitopes (PLP 178–191). Enhanced proliferation and epitope spreading may explain the posttreatment exacerbation seen in all VLA-4 blocking treatment protocols. This posttreatment exacerbation of disease corresponds to significant increase in the histopathology in the CNS, including enhanced lymphoid cell infiltration, amplified expression of VCAM-1, and increased proinflammatory cytokine messenger ribonucleic acid (mRNA).

Unfortunately, extension of the treatment to 44 days in R-EAE did not improve the outcome. Disease exacerbation began even before treatment ended, resulting in accumulation of highly activated T cells circulating in the periphery and invading the CNS. These studies suggest multiple functions for VLA-4 binding and advise caution when bringing these biologics into clinical trials.

Based on the work done in R-EAE, expectations for VLA-4 blockers might be low. In fact, the results of clinical trials in relapsing MS were encouraging, resulting in 50% reduction in relapses in these patients [23, 24]. This led to early approval of natalizumab

(TYSABRI) by the FDA in 2004, prior to the completion of these phase III trials. As in our R-EAE model, MS patients on TYSABRI did exhibit increased indicators of peripheral T-cell activation including significantly increased numbers of cells secreting proinflammatory cytokines TNF-α and IFN-γ [25]; however, to date, thousands of patients have been receiving TYSABRI for well over 2 years, presenting with few serious side effects, with one puzzling exception [26, 27]. Two patients with MS and one patient with Crohn's disease (CD) were diagnosed with progressive multifocal leukoencephalopathy (PML).

PML is a demyelinating disease caused by the JC virus. This virus is a common human virus persisting in renal and CNS tissue of approximately 80% of the world population. This virus can be reactivated in severely immunocompromised patients (PML) and may be associated with gastrointestinal cancers [28].

Although initially pulled off the market, due to the great promise of natalizumab, in 2005 the FDA reapproved this biologic for use in relapsing MS. In addition, thousands of Crohn's patients are receiving natalizumab with promising results. In the future it will be important to monitor both the increased peripheral activation of proinflammatory cells and the possible reactivation of latent viruses in patients receiving reagents designed to block migration of activated cells into an inflammatory region such as the CNS (MS) or the gastrointestinal tract (CD).

## 12 MODELS OF CARDIOVASCULAR DISEASE AND METABOLISM

Numerous animal models exist for studying blood pressure regulation, stroke, and metabolic disease. Some models have developed spontaneously in mice, rats, or other species. Some have been created through selective inbreeding and others through modern genetic manipulations to create transgenics, consomics, and knockouts. Still other models use surgical, chemical, or dietary alterations to create a disease state. The gold standard animal models listed in Table 1 were chosen based upon the extent of their use in biomedical research and their proven utility. With the exception of the streptozotocin-induced type diabetes, the models chosen were created through inbreeding or via spontaneous mutations. It is the opinion of the authors, that such models best represent the heterogeneity associated with human disease states as compared to transgenic and knockout models.

References listed in Table 1 are, for the most part, review articles, describing phenotypic or genotypic alterations in the animal model or intervention studies used to treat the disease state. Table 2 lists some of the major suppliers of animals for research purposes. Neither table is exhaustive. Suppliers listed in Table 2 are those with which the authors have experience. In addition to these and other commercial vendors, animal colonies, especially transgenics and knockouts, may be obtained from individual investigators or research facilities. Below is a brief synopsis of selected models. Some of the vendors' websites contain additional information about the strains and other information that the reader will find useful for selecting or developing an animal model that fits specific genotypic or phenotypic characteristics.

The spontaneously hypertensive rat (SHR) is by far the most widely used animal model for studying the development and treatment of hypertension. It was developed by selective litter mate pairing for hypertension from the wister kyoto rat (WKY) in the 1960s at the Okmato, Kyoto School of Medicine in Japan. Colonies have been in the United States since the late 1960s and can be obtained as an inbred or outbred rat from several commercial vendors. The WKY is the traditional normotensive control rat used when studying the SHR. Hypertension in these rats is multifactorial because of the breeding and selecting for high blood pressure—similar to most human cases of essential hypertension. Although the WKY is the traditional control rat used with the SHR, it is not ideal. During the development of the strain, hypertension was selected for and inbred, whereas the normotensive WKY parent colony was kept as an outbred colony. Thus, there is more genetic diversity within the WKY than SHR. Moreover, chance selection of nonhypertensive genes due to the bottleneck of inbreeding has lead to selection of genotypic and phenotypic features unrelated to hypertension. Another distraction from the SHR is that the kidney shows limited signs of hypertensive-related nephropathy. Thus, the SHR can be considered a model of renal protection against hypertensive nephropathy as compared to surgical or pharmacological models of comparable blood pressures.

Substrains of the SHR have other interesting and useful characteristics. A few substrains exhibit a high incidence of cerebral hemorrhaging and are thus termed stroke-prone SHR. The incidence of stroke is mainly seen in males, where the incidence rate can be as high as 82%.

The SHR is considered a salt-insensitive form of hypertension since blood pressure increases under a normal salt diet and is affected little by increases or decreases of salt in the diet. It also exhibits many signs of diabetes, such as insulin resistance, and hyperinsulemia. This appears to be a recurring theme in hypertensive models, suggesting that the development of

hypertension may have an underlying metabolic component. Although the SHR is considered to be salt insensitive, crossing of the SHR with normotensive rats, such as the WKY, results in an F1 generation, the borderline hypertensive rat (BHR) that is salt sensitive and hyperreactive to stimuli. The BHR will develop increased blood pressure in response to various stresses, such has a high-salt diet, noise, crowding, or mild air jets blown at it. Kidneys of the F1 generation show more signs of renal injury due to increased blood pressure than the parent SHR strain.

The Dahl salt-sensitive (DSS) and salt-resistant rat (DSR) strains were originally developed Lewis Dahl and then maintained as an inbred colony by John Rapp in the early 1970s by selectively inbreeding litter mates after selection of salt sensitivity or salt resistance to increased blood pressure. Unlike the SHR, both the DSS and DSR were maintained as inbred colonies as the strains were being developed. The DSS rat shows normal or slightly elevated blood pressure when maintained on a normal rat chow diet. When exposed to a high-salt diet (typically 8%), the blood pressure rapidly and progressively increases. Many of the rats will exhibit cerebral hemorrhaging if kept on a high-salt diet for prolonged periods. They are also subjective to moderate-to-severe renal nephropathy in response to the high-salt diet.

Harlan Laboratories was the sole commercial provider of Dahl rats. In the mid-1990s there was a breeding mishap in one of the expansion colonies resulting in a DSS hybrid [103]. The vendor has since re-derived the strain from unaffected colonies. Charles River also maintains a colony of DSS and DSR rats that originated from the Harlan colony prior to the mishap and has been cleared of genetic impurities.

The OB/OB and DB/DB mouse strains are models used for obesity and type II diabetes. They are spontaneous mutations of the leptin gene and the leptin receptor gene, respectively. Both mutations end up creating a nonfunctional protein. Although leptin has been shown to be central in maintaining a lean body mass and normal metabolism in mice, its role is more limited in humans. Nonetheless, both mouse models exhibit the classic phenotypic signs associated with obesity and type II diabetes in humans. Thus, while the etiology of obesity and type II diabetes is more heterogenic than in these mouse models, the phenotypic similarities makes them useful targets for the study of the onset of secondary pathologic conditions associated with diabetes or for pharmacologic intervention.

## 13 KNOCKOUT AND TRANSGENIC ANIMALS AS ANIMAL MODELS OF HUMAN DISEASE

With the development of DNA (deoxyribonucleic acid) technology, large numbers of designer mice and rats can now be created. These animals can serve as interesting and informative animal models of human disease and range from addition of a human gene (transgenic) to deletion of a functional gene (knockouts). Use of these animals in testing pharmaceuticals must be done with caution.

As scientists learn more about the molecular etiology of certain diseases, the opportunity to create animals with similar molecular abnormalities opens a new avenue of research. Alison Abbott, in *Nature*, summarizes some of the exciting new animal models in the study of several psychiatric disorders such as depression and schizophrenia [75]. Many such disorders are diagnosed and described by very nonobjective criteria. This includes overlapping symptoms and little characterized pathology in terms of anatomy or molecular etiology. This vague characterization has led to the use of animal models that seem to some to be inadequate as models for human disease.

The advent of increased knowledge of the molecular deficiencies and the identification of candidate susceptibility genes in various human diseases have lead to the creation and development of more useful mouse models for study. The *Disc* gene is a strong candidate gene for schizophrenia. Transgenic mice with a disrupted *Disc-1* gene show anatomical similarity to human schizophrenia, with enlarged brain ventricles. The Sapap3 knockout mice groom themselves until they bleed, modeling compulsive-behavior syndromes. Because these mice demonstrate physical and molecular similarities to human psychiatric disorders, scientists anticipate their use in more successful pharmaceutical trials in the future.

Immunology is another focus for creation of transgenic and knockout animal models. Many cytokine knockout mice and major histocompatability class (MHC) I and II transgenic mice have been created, and many of these genetically manipulated mice present with autoimmune disease (13, 42). Similarly, various transgenic and knockout mice have been developed by numerous investigators examining hypertension, obesity, diabetes, and other disease processes. Many more models have been created strictly for basic research, examining the function of a specific protein or other factor. In fact, so many genetically manipulated animal models exist that we would be unable to list them all in this chapter. In addition to the major providers of traditional animals, Taconic Farms Inc. produces thousands of transgenic and knockout mice used as animal models of disease (Table 2).

These genetically manipulated animal models exemplify the hope that basic research will lead to the discovery of new mechanisms of disease. Characterizing diverse molecular pathological pathways may result in new families of drugs targeting very different aspects of disease. The goal of this research is to increase the number of different drugs tested in animals that go on to be successful and safe in human trials. In most, if not all cases, transgenic and knockout models do not represent the human condition. Moreover, the phenotypic expression of a transgenic or knockout animal is often dependent upon the animal strain used. Thus, the phenotype is dependent upon the genetic background on which they were created. They can be of extreme value and function for studying the function of a particular factor but have limited utility as a "gold standard" animal model for pharmaceutical or therapeutic purposes.

## 14 ARE ANIMAL MODELS USEFUL?

Many groups of citizens, physicians, and scientists are demanding change in preclinical drug testing. Often these groups focus on using techniques other than animal models, such as human cell/tissue methods and computer modeling. As is often the case when change is required, throwing out old methods for the new is popular but not practical or wise. The use of computer models is limited by the existing knowledge used to create those models. The more information gained from biological and chemical discovery, the more useful the computer models. Their value in drug development is unquestionable, once the structure of the target compound is known, or analysis of several known agonists or antagonists reveals key structural or chemical features that can be used to create newer and potentially better drugs. Once created, however, they must be tested in vitro and in vivo. What often looks good in a computer model has unanticipated results or side effects when tested in a real-world environment.

As discussed in this chapter, much can be gained by making smart use of several good animal models. However, these animal experiments must be augmented with human-based in vitro experiments, good toxicity databases, and computer modeling technology. Differences in animal and human cells do result in differences in the efficacy and toxicology of certain drugs. The old industrial adage does hold true for the development of drugs and other therapeutics—"cheaper, faster, better." It is accomplished by the use of computer models, in vitro testing using human cells or cell lines, and gold standard animal models, before human trials begin.

## 1 INTRODUCTION

Vaccination has had a profound effect in alleviating human morbidity and mortality since the approach was widely introduced in the nineteenth century. The objective of vaccination is to administer a vaccine in such a way as to induce a protective immune response against the corresponding pathogen. Live attenuated and inactivated viral and bacterial vaccines were successful against a number of major pathogens including smallpox, polio, measles, and pertussis. However, together with the major advances in molecular genetics and immunology, safety concerns associated with live and whole-cell killed vaccines have driven a quest for "subunit" vaccines that are based on isolated components of microbes. Despite their advantages in terms of safety, these vaccines are generally ineffective when administered alone, necessitating the use of substances (adjuvants) that can enhance immunity. Alum is the most widely used vaccine adjuvant and is very effective at promoting antibody responses and Th2 type T cell responses. However, it is now recognized with a number of major diseases, including tuberculosis and malaria, that strong cell-mediated immunity is important for protection so adjuvants that can effectively drive such responses and not only antibody responses are required [1]. The global vaccine market is projected to grow very strongly over the next decade so there will be an increasing demand for a range of potent and effective vaccine adjuvants.

## 2 HISTORY OF ADJUVANT DISCOVERY

Adjuvants were originally defined as "substances used in combination with a specific antigen that produce more immunity than the antigen alone" [2]. The modern field of adjuvant research emanated from studies carried out by Gaston Ramon at the Pasteur Institute in the early 1920s that demonstrated that the injection of an eclectic variety of substances including tapioca, inorganic salts, oil, and pyogenic bacteria with diphtheria toxoid enhanced antibody responses to the toxin [3, 4]. Soon afterward Glenny and co-workers reported that injection of diphtheria toxoid as an alum precipitate induced significantly higher antibody responses than injection of the toxoid alone [5–7]. This seminal observation on the adjuvant properties of aluminum compounds ushered in the use of these mineral salts, and these still form the basis of the most widely used adjuvants today. Indeed these remain the only vaccine adjuvants currently licensed by the U.S. Food and Drug Administration (FDA).

The next significant advance in adjuvant research was the description by Jules Freund of a water-in-mineral-oil emulsion containing killed mycobacteria [8]. This is commonly known as Freunds complete adjuvant (FCA) and is a highly potent adjuvant although associated with unacceptable side effects. As a result, a formulation without the killed bacteria was developed and has been used clinically [9, 10]. However, newer emulsions have since been developed and Freunds

incomplete adjuvant (FIA) is not used in prophylactic vaccination. FCA was the first adjuvant that deliberately included killed pathogens or pathogen-derived factors and thus may be considered the first "immunostimulatory" adjuvant.

The ability of pathogen-derived and other substances to promote inflammatory responses can be traced back to much earlier studies. Lydia Rabinowitsch in 1897 demonstrated that injection of *Mycobacterium butyricum* led to local granulomatous reactions at the injection site and that the extent of this reaction was exacerbated by the addition of paraffin oil or butter [11]. This was supported by subsequent work showing that killed mycobacteria exerted nonspecific immunostimulatory effects [12]. However, the description of the adjuvant properties of bacterial lipopolysaccharide (LPS) [13, 14] and mycobacterial peptidoglycan [15] was a major advance as it demonstrated the immunostimulatory properties of isolated pathogen-derived factors.

The field of vaccine adjuvants is going through a "golden age" at present due in part to the developments in immunology. After almost 100 years of largely empirical developments in adjuvant research and development largely due to a poor understanding of how adjuvants work, the field is now developing on a new more rational plane.

## 3 REQUIREMENTS OF ADJUVANTS

Adjuvants must satisfy a number of criteria to be considered for clinical use. Safety is a central factor, and there is frequently a fine balance between potency and toxicity. Local reactions that have been described with adjuvants have included pain, inflammation, necrosis, lymphadenopathy, granulomas, ulcers, and sterile abscesses [16, 17]. These have mainly been associated with Freunds complete and incomplete adjuvants while aluminum hydroxide and aluminum phosphate generally do not lead to serious local pain or damage. The effects of the adjuvants are influenced by the associated antigens; thus, it is now recognized that the safety of adjuvant–antigen combination must be tested to establish safety on a case-by-case basis [18].

In terms of the immune responses induced, adjuvants can achieve a number of objectives that include enhancement of antibody and T-cell responses, increased duration of response, induction of memory responses, reduction in vaccine dose, facilitate vaccination by alternative routes, and exert control over the type of T-cell or antibody response induced [19]. The ability of adjuvants to reduce the dose of vaccine required to induce protective immunity "dose sparing" has been highlighted recently in relation to the production of sufficient vaccines to enable global coverage with avian influenza vaccines [20]. In many cases vaccines are not optimally effective in neonates and the elderly. For example, there is evidence that influenza vaccines are less effective in aged populations [21]; here again adjuvants may be used to allow successful vaccination of these age groups.

## 4 IMMUNOLOGICAL REQUIREMENTS OF VACCINES

In the past the efficacy of adjuvants, including alum, emulsions, liposomes, and microparticles, was attributed to a "depot effect" enabling sustained presentation of vaccines to the immune system. It is now clear that activation of innate immune responses is essential to drive adaptive immune responses including helper T cells and antibody responses. Dendritic cells (DCs) occupy a central position in studies of the mechanism of adjuvant action as these cells are key in priming naïve T cells [22]. The activation and polarization of T-helper-cell responses by dendritic cells requires three signals: Signal 1 is provided by the interaction between specific peptides presented in the context of major histocompatability complex (MHC) class II to the T-cell receptor, signal 2 comprises the interaction of co-stimulatory molecules on activated DCs with their cognate ligands on T cells, and signal 3 represents polarizing cytokines released by DCs [23]. T-cell polarization is strongly influenced by cytokines produced by DCs but also by other cells including natural killer cells. Interleukin-12 (IL-2) production promotes the differentiation of T helper cells type 1 (Th1 cells), which produce interferon-γ and IL-2 and promote cell-mediated immunity, activation of $CD8^+$ cytotoxic T cells, and complement fixing antibody [24]. Th2 cells are promoted by IL-4 and characterized by production of cytokines including IL-4, IL-5, and IL-13 and provide help for B-cell production of IgG1, IgE, and IgA antibodies (IgE and IgG4 in humans) [24]. A recently described population of Th17 cells produce the proinflammatory cytokine IL-17 and play roles in antimicrobial immunity, particularly in promoting neutrophil infiltration [25]. The differentiation of these cells is promoted by the cytokines IL-23, IL-1, transforming growth factor (TGF)-β, and IL-6. Regulatory T cells including antigen-specific Tr1 and Th3 cells are promoted by IL-10 and TGF-β and play roles in regulating inflammatory responses and maintaining the balance between tolerance and immunity [26].

## 5 ACTIVATION OF INNATE AND ADAPTIVE IMMUNITY BY ADJUVANTS: STRANGER AND DANGER MODELS

Despite the enormous body of work on vaccine-specific immunity and adjuvants, the vital role of innate immunity in the mechanism of adjuvant action and in promoting protective immune responses was not appreciated until relatively recently. In particular, it was the insight of Charles Janeway who observed that adjuvants, which he termed immunologists' "dirty little secret," activated innate immune responses and dictated the ensuing adaptive immune response, which provided an important conceptual framework for the mechanism of adjuvant action [27]. Janeway proposed that conserved elements of infectious organisms, or *pathogen-associated molecular patterns* (PAMPs), were recognized by the immune system by specific receptors, *pattern recognition receptors* (PRR). Many of the adjuvants now in preclinical and clinical trials are based on such PAMPs. The interaction of PAMPs with PRR on dendritic cells leads to activation of the cells and licences them to provide signals 1, 2, and 3 to drive T-cell activation and polarization. The discovery of PRR, including Toll-like receptors, Nod-like receptors, and Rig I-like receptors [28] has shone tremendous light on the mechanism of action of a number of adjuvants.

A competing or possibly complementary theory for how the immune system is activated was formulated in Polly Matzinger's "danger model," which proposed that endogenous mediators released by stressed or damaged cells activated innate and subsequently adaptive immunity [29]. This latter theory may explain how adjuvants and delivery systems that do not derive from PAMPs or bind to specific receptors on immune cells can serve as effective adjuvants. The potential role of danger as proposed by Matzinger on the efficacy of vaccines may be traced back to the 1920s when Ramon made the observation that higher antidiphtheria toxoid antibody titers were induced in horses that developed an abscess at the inoculation site and that generation of an abscess by the injection of unrelated substances with the diphtheria toxoid increased antibody responses against the toxoid [30]. Further support for a role of "danger" in promoting immunity came from a study by Dienes and Schoenheit showing that injection of protein antigens into guinea pigs infected with *Mycobacterium tuberculosis* induced a strong delayed-type hypersensitivity reaction after sensitization with the same antigen [31]. In 1937, Jules Freund reported elevated antibody titers in tuberculous guinea pigs injected with sheep erythrocytes [32]. This prompted studies into the effect of emulsifying an aqueous solution of the antigen ovalbumin in paraffin oil containing killed tubercle bacilli with the aid of a surfactant [32, 33]. The work culminated in the development of Freund's complete adjuvant, a water-in-oil emulsion of mineral oil, the surfactant mannide monooleate, and heat-killed *M. tuberculosis* or derived bacterial components [8]. This work established the efficacy of emulsions in vaccine delivery and demonstrated the added potency of incorporating pathogen-derived factors to the system. This series of studies demonstrated the requirement for pathogen-derived danger signals and/or local inflammatory responses to promote strong adaptive immune responses to antigens.

## 6 TYPES OF ADJUVANTS

There have been many attempts to classify adjuvants into groups, but this is not an easy exercise since many "delivery systems" have immunostimulatory effects and some systems can fulfill a number of functions. However, for the purposes of this chapter, we classified adjuvants into *immunostimulatory adjuvants*, which can in most cases be shown to interact directly with specific receptors on antigen-presenting cells, and *particulate delivery systems*, which are defined principally by their particulate nature. However, an increasing body of evidence indicates that many of these systems also exert specific effects on innate immunity.

## 7 IMMUNOSTIMULATORY ADJUVANTS

### 7.1 Pathogen Derived

***Toll-Like Receptor (TLR) and Nod-Like Receptor (NLR) Agonists*** Toll-like receptors recognize microbial associated molecular patterns and trigger innate immune responses. To date 13 of these receptors have been identified in mammalian cells [28]. Among the first microbial products investigated for immunostimulant activity were components of the tubercle bacillus and other related mycobacteria [34]. A series of biochemical studies ultimately led to the identification and isolation of trehalose dimycolate (TDM), also known as cord factor, which has adjuvant properties [35]. Ribi adjuvants, which are highly potent but only used experimentally, contain this high-molecular-weight glycolipid, which is extracted from saprophytic, noncording *Mycobacterium phlei* cells [36]. The immunostimulatory activity of released cell wall lipids in Bacillus Calmette-Guérin (BCG) is principally associated with trehalose mycolates [37]. Cell wall skeleton (CWS), a mycobacterial cell wall extract from which the loosely bound lipids,

proteins, and carbohydrates have been removed is a potent immunostimulator that works independently of free TDM [38]. The immunostimulatory activities of CWS and whole mycobaterial cells can be at least partly attributed to the presence of a polymerized form of muramyl dipeptide (MDP). MDP is recognized by the Nod-like receptor Nod2, leading to the induction of intracellular signaling cascades and inflammatory responses [39]. MDP has been shown to promote antigen-specific antibody production and cell-mediated immunity in addition to increased nonspecific immunity to bacteria, viruses, fungi, and parasites [40]. MDP was successfully used as an adjuvant in a veterinary vaccine against leishmaniasis [41].

***Lipopolysaccharide-Derived Adjuvants*** Lipopolysaccharide (LPS) is a component of endotoxin in the cell wall of gram-negative bacteria, such as *Escherichia coli*. The discovery that LPS could enhance antibody responses to coadministered antigens was discovered over 60 years ago [14], and the ability of killed bacteria and LPS to mediate nonspecific immunostimulatory effects has a similarly long history [42], although the full significance of these findings has only been appreciated relatively recently. LPS is recognized as a very effective adjuvant for protein antigens and can promote both humoral and cell-mediated immunity. However, endotoxins are unacceptable for human use because of their toxicity. The lipid A component of LPS is responsible for most of its biological activities [43]. Lipid A and certain synthetic derivatives with diminished toxicity resulting from the substitution of fatty acids and removal of phosphate groups increase humoral and cell-mediated immune responses [44, 45]. Monophosphoryl lipid (MPL) A is derivative of LPS that retains immunostimulatory activity but with considerably reduced toxicity and has been widely used clinically [46]. Due to its effective adjuvant properties and safety record in clinical trials, MPL is likely to be approved as an adjuvant in the near future for clinical use and is currently used together with alum in the Fendrix, hepatitis B vaccine from GlaxoSmithKline (GSK), which is approved in Europe [47]. Second-generation, low-toxicity derivatives of LPS are also under study such as RC529 [48], a derivative of which has been included in a candidate HIV (human immunodeficiency virus) vaccine clinical trial [49].

***Other TLR Agonist-Based Adjuvants*** A wide range of other pathogen-derived immunostimulatory adjuvants are being investigated as adjuvants. These include Pam3Cys (TLR1/2 agonist), poly I:C (TLR 3), imidazoquinolines including imiquimod and resiquimod (R848) (TLR7/8 agonists), and unmethylated CpG oligodeoxynucleotides (TLR9). Imidazoquinolines and unmethylated CpG oligonucleotides induce Th1 responses following signaling initiated via TLR4, TLR7/8, and TLR9, respectively. In addition to the well-established use of resiquimod and imiquimod, new synthetic TLR7/8 agonists including 3M-019 have been produced and are being tested [50]. Currently, a CpG adjuvanted vaccine against malaria is also being tested in humans. [51] This field is going through a period of tremendous growth with multiple synthetic ligands for pathogen recognition receptors currently being tested. A full discussion of this area is outside the scope of this chapter; the area has been excellently reviewed recently [52].

***QS21*** QS21 is an immunostimulatory adjuvant but of plant origin, and, in contrast to a number of the foregoing examples, no specific receptor for QS21 has yet been identified. Saponins are a heterogeneous group of sterol glycosides and tripernoid glycosides distributed throughout the bark, stem, roots, and flowers of many plant species. Humans have used saponins for many applications for hundreds of years. For example, saponins were used in Africa to kill snails infected with schistosomiasis [53]. The adjuvant property of saponins was first demonstrated in the early 1920s by Gaston Ramon [4]. In the1950s Espinet included saponins in a veterinary vaccine against foot-and-mouth disease [54]. The adjuvant-active fraction of saponins from the bark of a tree found in South America, *Quilaja saponaria* Molina, was identified by Daalsgard and named Quil A [55]. Further analysis of Quil A showed that it was a heterogeneous mixture of saponins, making it unsuitable for human use. In 1991 Kensil and co-workers isolated 22 fractions from Quil A using reverse-phase high-performance liquid chromatography (RP-HPLC). QS21 [56] has proved to be the most promising as a vaccine adjuvant due to its strong immunostimulatory activity and reduced toxicity. Studies involving QS21 suggest that it acts as an immunostimulatory adjuvant rather than an antigen depot [57, 58]. Murine studies using QS21 as an adjuvant have shown that it has the ability to induce the Th1-associated antibody isotype, IgG2a, and potent cytotoxic T lymphocyte (CTL) activity, giving it an advantage over a number of other adjuvants that lack the ability to induce strong cell-mediated immunity. [59]. QS21 also has the ability to induce mucosal immunity following intranasal immunization [60]. The mechanism of action of Quil A is not currently well understood. With its strong adjuvant activity, low toxicity, and ability to induce cell-mediated responses, QS21 has significant potential for use in human vaccines. A phase I/II trial involving QS21 and melanoma antigens is currently underway in the United States [61]. QS21 has also been tested in a therapeutic vaccine for

advanced pancreatic cancer and colorectal cancer. Phase I has just been completed and results are pending [62]. Thousands of subjects have received QS21, and only minor side effects have been registered such as pain around the injection site. This work is focused principally on therapeutic vaccines for cancer. However, the possible application of QS21 in infectious diseases is also under active investigation. In fact, QS-21 is currently being evaluated in more than 20 vaccine indications, several in late-stage clinical trials [63].

### 7.2 Particulate Vaccine Adjuvants and Delivery Systems

***Mineral Salts*** Aluminum phosphate, aluminum hydroxide (generally referred to as alum), and calcium phosphate are used clinically to enhance immunity to vaccines. Alum has been widely used in human vaccination for more than half a century during which time billions of doses have been administered, particularly in diphtheria, tetanus, and pertussis vaccine (DPT), *Haemophilus influenzae* B and, IPV vaccines [64]. The early work by Glenny and co-workers focused on alum precipitates [5]. However, efficacy with such preparations was variable and pre-formed aluminum-hydroxide hydrated gels were developed that are effective in protein adsorption, can be pre-formed, and act reproducibly [65]. Aluminum phosphate is also used and a pre-formed aluminum phosphate gel preparation is an effective adsorbant and adjuvant [16], and calcium phosphate has also been established as comparable to alum in terms of efficacy [66]. Alum is generally given by intramuscular injection, and it has been reported that granulomas occur if the adjuvant is administered via subcutaneous or intradermal routes [67].

Despite decades of widespread use, the mechanism by which alum activates the immune system is not well understood. Alum is a very effective inducer of antibody responses but is less effective in the induction of cell-mediated immunity. The strong induction of Th2-type responses indicates that the adjuvant may exert specific effects on the immune system in addition to acting as an antigen "depot". Injection of alum promotes the secretion of IL-4 by splenic Gr1-positive cells [68], and its induction of T-cell proliferation relies on IL-1 [69]. Indeed, it was recently found that alum can promote the secretion of IL-1 and IL-18 by antigen-presenting cells ([70] and our unpublished data).

Injection of alum in humans causes adverse reactions, including local pain and fever [66, 71]; however, whether this enhances vaccine efficacy is unknown. The "danger theory" proposes that tissue and cell damage releases intracellular factors with powerful immunostimulatory properties [72]. We have preliminary data demonstrating that tissue necrosis occurs around the alum injection site and that high concentrations of alum are toxic to murine cells (manuscript in preparation). Thus, there may be a role for endogenous danger signals in the mechanism of action of alum and related adjuvants.

Alum is a highly effective and safe adjuvant for a number of vaccines, but it is not universally effective. The adjuvant is not optimally effective for use with peptide vaccines [64], and poor efficacy was documented using alum with influenza and typhoid fever vaccines [73, 74]. Furthermore, due to its Th2 bias in promoting adaptive immunity, alum is not suitable for vaccines against diseases such as tuberculosis, HIV, and malaria where potent cell-mediated immunity is critical. However, there are indications that when alum is combined with other adjuvants, it is more effective in promoting Th1-type T-helper-cell responses [75, 76].

***Emulsions*** The use of emulsions in vaccines to boost immune responses can be traced back to work by LeMoignic Pinoy in 1916 who used the first oil emulsion, water, and vaseline, with inactivated *Salmonella typhimurium*. [77]. Less then 10 years later Ramon demonstrated that starch oil increased antibody responses to diphtheria toxoid [4]. In the 1930s Freund developed paraffin-oil-based emulsions with or without heat-killed *Mycobacteria*, producing Freund's complete or incomplete adjuvant, respectively [32]. Freund's adjuvant is an example of water-in-oil (W/O) emulsion, which is made up of antigen-containing water droplets in a continuous oil phase. Oil-in-water (O/W) emulsions are composed of antigen in a water phase with oil droplets in the solution, and double emulsions can be produced with water droplets trapped within larger oil droplets dispersed in a water phase (W/O/W) [78]. Herbert showed that O/W emulsions have the ability to retain an antigen at the site of injection, allowing prolonged exposure to the immune system [79]. Oil-in-water emulsions have shown the best safety profile, while mineral oil emulsions have proven too toxic for human use. Syntax adjuvant formulation, or SAF, is an oil-in-water adjuvant developed in the 1980s as a possible replacement for Freund's adjuvant. SAF contains the biodegradable oil, squalene, but was too toxic for clinical use due to the presence of muramyl dipeptide [80]. The toxic nature of SAF led to the development of a safer emulsion for adjuvant use known as MF59, a microfluidized O/W emulsion comprising squalene oil with Tween 80 and Span 85 as surfactants but with no additional immunostimulators [81]. MF59 has been shown to be a potent adjuvant with an acceptable safety profile. A large number of subjects have been immunized with MF59, and the adjuvant was well tolerated and was safe in newborns and the elderly [82]. FLUAD is an MF59 adjuvanted influenza vaccine

currently licensed for use in the elderly by 12 European health authorities and in some non–European Union EU countries, with 25 million administered doses to data. [83] Novartis is also using MF59 in a candidate H5N1 vaccine [84] and claims that it can significant reduce the required "dose sparing" and also induce cross-serotype specific immunity. Furthermore, Sanofi-Pasteur claims that its proprietary emulsion-based adjuvant for their candidate H5N1 vaccine facilitated the use of 10-fold less antigen then conventional vaccines [85]. There is strong evidence from a number of companies that emulsion based vaccines are effective for pandemic flu vaccines [86].

***ISCOMs*** In 1971 immune-stimulating complexes, or ISCOMs, were first visualized by electron microscopy in a preparation of virus particles treated with saponin [87]. However, it was not until 1984 that Morein et al. first described the formation of these saponin-containing complexes with viral membrane proteins [88]. Negative stain electron transmission shows these well-defined particles as spherical, cagelike structures of approximately 40 nm in diameter [89]. Their formation occurs spontaneously upon mixing cholesterol, *Quilaja saponaria* saponins, and phospholipids. It is the interaction of the cholesterol and saponins that forms the matrix of these particles, and phospholipids are added to produce a less tightly compressed particle, allowing for the insertion of amphiphatic molecules [90, 91]. ISCOMs are manufactured by and registered to Isotec AB, which has also developed ISCOMATRIX, which consists of cholesterol, phospholipids, and saponins but lacks the viral membrane proteins allowing for the insertion of antigens into the particles [92]. ISCOM-based vaccines have been shown to induce both antibody and Th1-polarized cell-mediated responses and are particularly potent in the induction of cytotoxic T cells [89]. Watson et al. demonstrated that the trafficking of ISCOMs from the site of injection to the spleen and the local draining of lymph nodes was faster than protein alone [93]. However, the exact mode of action of ISCOMs remains largely unknown. Several theories have been suggested to explain their adjuvant activities: (a) delivery of the antigen directly to antigen presenting cells, (b) delivery of the antigen into the cytosol of the cell, allowing access to the MHC I pathway, which is required for $CD8^+$ T-cell development, and (c) induction of cytokine production by antigen-presenting cells; for example, ISCOMs have been shown to induce IL-6 and IL-1 production in macrophages [53, 94]. It has also been found that IL-12 and interferon-γ are key to the adjuvant activity of ISCOMs. [95]. However, to date no vaccine containing ISCOMs or ISCOMATRIX has been licensed for human use. Despite this, over 1000 people have been injected intramuscularly with ISCOM-based vaccines, and it was reported that they were safe and generally well tolerated, and side effects were found to be self-limiting [89]. Several ISCOM-based vaccine formulations are currently in development, including viral proteins from influenza, purified protein recombinants such as HPV16 E6E7 fusion protein, and NY-ESO-1, an antigen expressed in a wide variety of cancers [96, 97]. Results in trials so far involving these antigens have been positive, with 69–92% of subjects developing $CD4^+$ T-cell responses and virtually all subjects producing antibody responses irrespective of preexposure [96, 97].

Although ISCOMs have been widely used for veterinary patients, their reactogenicity is perceived as a problem in relation to clinical application. However, recent work demonstrated that GPI-0100, semisynthetic derivatives of deacylated Quilaja saponins (DS saponins) modified at the glucuronic acid residue retained immunostimulatory properties, indicating that synthetic derivatives with strong immunostimulatory properties may be developed [98]. Two different fractions induced Th1 and Th2 responses, respectively, suggesting that formulations may be tailored to the desired type of response.

***Biodegradable Microparticles*** Biodegradable, particularly poly(lactide-*co*-glycolide) (PLG) microparticles have been used for decades in sutures but also for drug delivery and controlled-release vaccine delivery systems [99]. The ability to enhance the immunogenicity of antigens by encapsulation into PLG microparticles was first demonstrated in the early 1990s [100, 101]. Microparticles can be formulated from a range of different polymers; however, PLG microparticles are the prime candidates for development as vaccine adjuvants [102]. PLG microparticles are biodegradable in vivo, undergoing nonenzymatic hydrolysis of the ester bonds to produce lactic and glycolic acids. The half-life of PLG microparticles is dependent on the molecular weight of the particle and the lactic-to-glycolic ratio and can range from days to weeks and possibly years. The optimal size range for vaccination is likely to depend on the application, but it has been proposed that microparticles of 1–3 μm are optimal in some settings [99]. During the microencapsulation process, antigens can be exposed to various potentially damaging conditions such as low pH, high shear, and organic solvents [103, 104]. This and the susceptibility of encapsulated antigen to acid-mediated hydrolysis [105, 106] encouraged scientists to develop alternative means of associating antigens with microparticles. O'Hagan et al. described the preparation of charged microparticles using sodium dodecyl sulfate (SDS) to produce

anionic PLG microparticles onto which it was easier to adsorb proteins [107]. Factors such as protein charge and hydrophobicity affect antigen adsorption and the optimal adsorption conditions are protein specific [108]. Cationic particles were developed by the same group that are optimized for the delivery of deoxyribonucleic acid (DNA) vaccines [109].

The exact mode of action of PLG microparticles is unclear; however, uptake by macrophages and dendritic cells seems to play an important role in their adjuvanticity [101, 110]. Injection of microparticles leads to uptake by inflammatory monocytes and migration and the differentiation of significant numbers of these cells into dendritic cells in draining lymph nodes [111]. Microparticles facilitate multimeric presentation of antigens on their surface, which is required for optimal B-cell activation. [112]. In addition to promoting strong antibody responses, studies in rodents indicate that PLG microparticles also effectively promote cell-mediated immunity [113, 114]. Cationic PLG microparticles have been tested in nonhuman primates as a delivery system for a hepatitis C vaccine and induced seroconversion in all animals vaccinated [115]. In addition cationic microparticles are currently being evaluated in a clinical trial with a candidate HIV vaccine [116].

***Liposomes*** Liposomes were developed in 1965 by Alec Bangham, who extracted lipids from egg yolk and found that when they were submerged into an aqueous solution they spontaneously rearranged as double-layered bubbles approximately the same size of a cell [117]. These "bubbles" were defined as liposomes, which are particulate structures composed of either natural or synthetic phospholipids. The biomedical applications of liposomes include drug delivery, vaccines, red blood cell substitutes for hemorrhagic injuries. Allison and Gregoriadis were the first to show that encapsulation of an antigen into a liposome led to increased antibody responses [118]. *Conventional liposomes* consist of a mixture of phospholipids and have been shown to be rapidly cleared by phagocytic cells of the reticuloendothelial system and macrophages [119, 120]. This discovery prompted the development of "stealthlike" liposomes that contain a small proportion of sterically stabilizing phospholipids and sometimes cholesterol, to further boost membrane stability and rigidity [121]. The increased stability of these stealthlike liposomes allows them to persist for as long as 2 days in the bloodstream after injection [121]. Physicochemical properties such as charge and fluidity of liposomes have been reported to have an effect on their immunogenicity. It may be possible to use liposomes to target specific cells of the immune system. For example, anionic liposomes with a bilayer composed of phosphatidylcholine, cholesterol, and phosphatidylglycerol or phosphatidylserine have been reported to interact specifically with human and murine dendritic cells [122]. *Immunoliposomes* allow for more specific targeting to cells as they contain a cell-specific monoclonal antibody incorporated into their membrane [122]. It has also been reported that monocytes express receptors for phosphatidylserine and that charged lipids bind selectively to dendritic cells. Findings to date also show that liposomes have the ability to promote access of antigens into both MHC class I and class II antigen presentation pathways, allowing the activation of both $CD4^+$ and $CD8^+$ T cells [123]. In 1992 the first demonstration of the effects of liposomal vaccines in humans was reported. Alving et al. immunized a group of 30 healthy males with a liposome-encapsulated recombinant protein ($R32NS1_{81}$) containing epitopes from *Plasmodium falciparium* [124]. The liposomes used also contained the immunostimulator monophosphoryl lipid A and were adsorbed to aluminum hydroxide. Overall, the vaccine was found to increase R32-specific antibody production compared with previous studies, and all reactions in volunteers were moderate [124].

Four liposome formulations are currently on the market for drug delivery in the treatment of Kaposi's sarcoma, metastatic breast cancer, and fungal infections in immunocompromised individuals [125]. The idea of lipid-based carrier systems for the delivery of antigens in vaccines has lead to the development of several alternatives to pure liposomes. Almeida et al. were the first to describe the intercalation of viral envelope proteins into conventional liposomes in 1975 [126]. Immunopotentiating reconstructed influenza virosomes, or IRIV, have proved to be a promising system for the delivery of antigens. These virosomes contain a fusion-active Hemagglutinin A (HA) protein within the membrane, which mediates pH-induced membrane fusion upon acidification of the endosome [127]. There are currently two marketed virosome-based vaccines in 29 countries worldwide. Inflexal V is a trivalent influenza vaccine, and Epaxal contains inactivated hepatitis A particles [128, 129]. Other lipid-based carrier systems include archeasomes, which contain archaebacterial lipid membranes, and proteasomes formed from reconstituted bacterial outer membrane proteins and cochleates [130]. A vaccine against follicular lymphoma using proteoliposomal technology has recently been used clinically. The proteoliposomes are constructed using proteins directly extracted from autologous tumor cells and lipids producing a patient-specific vaccine that can be formulated within one day. The vaccine was found to be safe and showed promise for this type of technology in the future [131].

## 8 FUTURE OF ADJUVANT RESEARCH AND DEVELOPMENT

Adjuvant research has a long history and many currently used adjuvants or products from which they were derived were identified prior to a mechanistic understanding of their modes of action. With developments in immunology and biochemistry and particularly an appreciation of the central role of innate immunity in adjuvant action, adjuvant research is now progressing on a more rational plain and is going through a golden age. Despite these developments, alum remains the only FDA-approved adjuvant, although this is likely to change and a number of additional adjuvants have been approved in Europe (Table 1). While many new adjuvants are likely to be identified through approaches such as TLR and NLR agonist screens [132] recent evidence indicates that identification even of relatively potent immunostimulatory molecules only constitutes the first step (Fig. 1). There are a number of promising particulate delivery systems in place, and one key approach is identifying synergistic interactions between these systems and immunostimulatory adjuvants. A number of recent clinical studies have demonstrated that the combination of particulate adjuvants such as alum and emulsions with TLR agonists or QS21 (AS02) induces significantly enhanced responses than these adjuvants alone (reviewed in [1]). An example of this is the use of alum and MPL (AS04) in Fendrix to prevent HepB in high-risk patients [47] and human papillomavirus 16/18 virus-like particles (Cervarix) to prevent cervical cancer [133].

While this review has concentrated on parenteral routes of vaccination, there are also great strides forward being made in transcutaneous and mucosal vaccine delivery. In particular, bacterial toxins or their derivatives are potent adjuvants for transcutaneous vaccine delivery [134, 135]. These toxins are also very effective adjuvants for mucosal vaccination, although clinical application has been delayed due to concerns over potential neurotoxic effects [136]. A number of other approaches are also being tested to enhance the efficacy of mucosal delivery of nonliving vaccines, including combinations of particulates and immunostimulatory molecules, protection of antigens from proteolysis, and specific targeting of vaccines to immune inductive sites [19]. In conclusion, this is an exciting time for adjuvant research, and we can expect the increased activity in the field to generate improved adjuvants for clinical use.

**TABLE 1 Examples of Adjuvants That Have Been or Are Currently Being Tested in Humans[a]**

| | Receptor | Applications | Status |
|---|---|---|---|
| | | *Immunostimulatory Adjuvants* | |
| RC529 | TLR4 | HIV | Phase III complete [49] |
| QuilA | ? | Advanced pancreatic and colorectal cancer | Phase I [62] |
| | | Melanoma antigens | Phase I/II [61] |
| MPL | TLR4 | Fendrix, Hep B mixed with alum | Licensed in EU [47] |
| | | Cervarix, HPV | Phase III [123] |
| CpG | TLR9 | Malaria | Phase I [51] |
| | | *Particulate Adjuvants/Delivery Systems* | |
| Mineral salts: Alum | ? | Diphtheria | Licensed [64] |
| | | *Haemophilus influenzae* B | Licensed [64] |
| | | IPV | Licensed [64] |
| Emulsions: MF59 | ? | FLUAD | Licensed [83] |
| | | H5N1 | Phase III [84] |
| ISCOMs | ? | HPV 16 E6E7 | Phase Ib [96] |
| | | NY-ESO-1 | Phase II [97] |
| Microparticles | ? | HIV Clade B | Phase I [116] |
| IRIV-based vaccines | ? | Inflexal V trivalent influenza vaccine | Licensed [128] |
| Proteoliposomes | ? | Epaxal hep A particles | Licensed [129] |
| | | Follicular lymphoma | Phase I complete [130] |

[a]The question marks in the second column refer to the fact that for many commonly used vaccine adjuvants no specific receptor has been identified on cells of the innate immune system.

**Figure 1 Strategy for the optimisation of adjuvants for vaccines.** By optimising the choice of immunostimulatory adjuvant and particulate delivery system, optimal, directed activation of innate immunity can be achieved. The type of system can be tailored to the specific requirements of a particular vaccine.

# ORAL DELIVERY OF MACROMOLECULES FOR THE DEVELOPMENT OF THERAPEUTIC AGENTS

Hye J. Lee and Chanmi Choi
*Hopkins Bio Research Center, Co., Seoul, South Korea*

## 1 INTRODUCTION

Oral delivery of macromolecules as therapeutic agents is still an unthinkable project for pharmaceutical scientists. However, considering the fact that developing peptides and proteins (major macromolecules) as medicines was also a mission impossible not too long ago, delivering macromolecules orally could not be just dreaming. Currently, over 160 protein-based therapeutics are available on the U.S. market and about 400 compounds are being developed [1]. Expenditures in the protein therapeutics market are predicted to continue to expand by 15–20% annually [2]. This is astonishing progress and could be attributed to the tremendous advances in recombinant DNA (deoxyribonucleic acid) techniques and biotechnologies. The dosage forms for peptide and protein drugs rely on their parenteral injection, which requires frequent administration, and are urging the development of more convenient dosage forms for non-invasive administration. An oral dosage form is the most preferable route because of the accompanying advantages of patient comfort, ease of administration, decreased medical costs, and increased patient compliance. Significant efforts in academic and commercial laboratories have been expended, but major breakthroughs in oral peptide and protein formulation achieving predictable and reproducible drug profiles in therapeutic doses without wasting up to 99% of the drug have not been achieved yet. The major barriers to developing oral formulations for peptides and proteins include poor intrinsic permeability, luminal and cellular enzymatic degradation, rapid clearance, and chemical and conformational stability [3]. Conventional approaches to address these barriers have not readily translated into effective peptide and protein formulations [4].

This review will provide an overview of the existing approaches, the recent advances that have been made in oral delivery as related to proteins, and some future directions to consider followed by reviewing factors affecting oral protein absorption. It is likely that effective oral formulations for peptides and proteins will remain highly compound specific, but the principal concept into preserve protein integrity before its reaches systemic circulation.

## 2 FACTORS AFFECTING ORAL PROTEIN ABSORPTION

Mechanisms of the absorption of peptides and proteins by epithelial cells are well described by Goldberg and Gomez-Orellana [5]. The process of receptor-mediated or non-receptor-mediated endocytosis (also called pinocytosis, when the material taken up is entirely soluble) is the most likely route of uptake and possible translocation of an orally administered therapeutic protein. Recent findings on many transporters add a transporter-mediated uptake as a possible absorption mechanism for proteins in addition to the paracellular absorption

mechanism [6, 7]. Oral delivery of particulates in which the protein drugs were embedded to be protected from the gut enzymes may require more understanding of uptake and/or absorption. Many groups believe that uptake of these particulates is a function carried out by membraneous/microfold (M) cells in Peyer's patches of the mammalian gut. However, other groups claim that uptake across the villous epithelium occurs via damaged regions or by a paracellular route [8]. Thomas et al. [9] found that the absorption of microparticles across the Peyer's patches of rats, mice, and rabbits can occur rapidly as microparticles can be detected in the lymph soon after intestinal delivery.

Numerous research studies during the last decade describe factors affecting low oral bioavailability of protein drugs [10–14]. The most advanced findings are summarized below. Effective and successful oral protein delivery requires further development in understanding these complex mechanisms in order to maximize the therapeutic potential of this class of compounds.

### 2.1 Absorption Site

In addition to metabolic differences, the anatomical, physiological, and biochemical differences between the various part of the gastrointestinal (GI) tract can cause significant variation in protein drug oral absorption [15, 16]. Among the physiological factors, regional differences in composition and thickness of mucus, pH, surface area, enzyme activity, bile, pancreatic juice, mucus, and fluid volume and content can modify dissolution rates, solubility, transit times, metabolism, and membrane transport of the drug molecules. The lipid/protein composition of the enterocyte membrane along the GI tract can alter binding and transport of drugs. The location and number of Peyer's patches, which are most abundant in the ileum, can also be important in the absorption of large molecules and particulate matters. Consequently, the existence of a (better) absorption window could not be a new discovery for peptide and protein drugs administered orally. For peptides, cyclosporine [17] and desmopressin [18] exhibited maximum absorption in the duodenum in humans and rabbits, respectively, while octreotide, a somatostatin analog, in the lower GI tract in humans [19]. Although little information exists on site-to-site variation in the protein absorption, the absorptive cells of neonatal rats have been shown to capture nerve growth factor [20], epidermal growth factor [21], milk proteins [22], ferritin and its analogs [23], and Follicle Stimulating Hormone-Fragment crystallizable region (FSH-Fc) fusion proteins by receptor-mediated endocytosis [24]. Some of the polymeric materials induce the opening of a tight junction between cells, which enables paracellular absorption to take place [5, 25–27]. Other enzyme systems, cytochrome P450 3A4 (CYP3A4) and catalytic activity decrease longitudinally along the small intestine [28], while P-glycoprotein (P-gp) messenger ribonucleic acid (mRNA) levels increase longitudinally along the intestine, with lowest levels at the stomach and highest levels in the colon [29].

### 2.2 Metabolism

A comprehensive review on the intestinal enzyme systems has been written by Woodley [14]. The greatest threat to therapeutic proteins lies in the lumen of the small intestine, which contains gram quantities of proteases secreted from the pancreas, as well as cellular proteases from the mucosal cells, which are constantly sloughed off from the villie. The second major enzymatic barrier is the brush-border membrane of the epithelial cells, which contains at least 15 peptidases that together have a broad specificity and can degrade both proteins and peptides. Woodley [30] suggested that an orally administered protein might encounter more than 40 different enzymes during passage through the small intestine. This is a qualitative assessment difficult to translate into quantitative information. Furthermore, lysosomal peptidases, estimated at over 60 in number, will also present a barrier to any peptides or proteins endocytosed by the epithelial cells. Considering the 30-amino-acid B chain of insulin and just 2 of the lysosomal peptidases, capthepsins D and B, exposure of the peptide to just these enzymes might lead to it being split at 20 sites out of a total of 29 [31]. Site-variable enzymatic degradation of luteinizing hormone-releasing hormone (LHRH) [32] and insulin-like growth factor (IGF-I) [33] were profiled.

Interestingly, Garrido et al. [15] have found that the hydrolytic activity for all enzymes (including the subcellular fractions of the aminopeptidase activities) and absorption rates from both the free amino acid and peptide solutions were reduced in bypassed jejunal segments. When large peptides and protein drugs were administered to the ileum, there was significant increase in absorption as compared to those drugs administered orally by gavage, supporting the possibility for heterogeneous distribution of the corresponding enzymes in the intestine [34, 35]. The colon has received some attention as a possible site for protein delivery; however, evidence shows that the lumen of the colon contains substantial amounts of peptidase activity, largely because of enzyme production by microorganisms. Therefore, intestinal metabolism acts as a concerted barrier to drug absorption. From knowledge of the enzymatic barrier, the strategies for oral protein delivery of enzyme inhibition and the synthesis of enzyme-

resistant protein analogs are logical developments. The latter approach seems to be a more realistic approach for protein drug oral delivery.

In addition, CYP3A4, the major phase I drug metabolizing enzyme in humans, and the *MFR-1* gene product P-gp are to be considered in designing the delivery system, which are present at high concentration in villus tip enterocytes of the small intestine and share a significant overlap in substrate specificity [36–38]. Cyclosporin, saquinavir, and a new cystein protease inhibitor of K02 (Morpholine-Urea-Phe-Hphe-Vinyl Sulfone; Axys Pharmaceutical) were metabolized by the CYP3A4 and P-gp system [36]. Fluvoxamine has prominent affinity for the CYP12 isozyme, lesser affinity for the CYP3A4 and CYP2C isozymes, and minimal affinity for CYP2D6 [39]. This profile suggests the need for careful dosage adjustment when used together with some drugs that have a narrow therapeutic range in order to minimize inhibiting their metabolism. Once they survive the intestinal enzymatic barriers, protein drugs have to face another presystemic metabolism, blood and hepatic extraction, although the transit time is shorter and the enzyme capacity could be smaller than those of the gut [40].

### 2.3 Permeability

The generally poor permeability of peptide and protein drugs across biological membranes can be attributed to their hydrophilic structure and large molecular size [3, 11, 41]. The mucosal cell permeability determines the rate of entry into the mucosa across the brush-border membrane. The permeation process can be carrier mediated and a paracellular or transcellular route. Although no quantitative cross correlations are established between human and animal permeability, tissue culture (e.g., the Caco-2 cell), permeabilities, and physicochemical properties such as partition coefficient, advancement in research in these areas has been exploitied by many investigators, indicating the availability of an informative database in the near future. Poor membrane permeability of hydrophilic proteins might be overcome by structurally modifying the compounds, thus increasing their membrane partition characteristics and/or their affinity to carrier proteins [42]. A variety of permeability enhancers for peptides [3], including salicylates, mixed bile salt–fatty acid micelles [43], chelators [44], fatty acids, bile salts [44], acylcamitines, medium-chain glycerides, surfactants [45, 46], and melittin [47] have been shown in cellular and animal models to increase the absorption of the peptides.

Cylcodextrins (CD) are cyclic oligomers of glucose that form inclusion complexes with drugs and cause alveolar epithelial membrane to increase the permeability based on their capacity to alter fluidity [44]. The surface charge of a polymer loaded on active compounds should be appropriately selected for the ability of permeability [48]. These enhancers are not warranted to work for protein drugs, however, it can be helpful to find a starting point for protein drug delivery.

### 2.4 Transporters

The distribution and characteristics of the intestinal transporters exhibit regional differences along the intestine, implying diverse physiological functions and in some cases pathological responses. There have been several studies on the mechanism and substrate structure–affinity relationship for this transport system [36, 49–52]. The cloning, expression, and characterization of individual peptide transporters will give additional insight into the rational design of drug molecules as well as the delivery system-especially for prodrug approaches [37, 53]. Functional expression of the multidrug resistance gene product, P-gp, as a primary active transporter in the intestinal brush-border membrane leads to net secretion of some drugs such as anticancer agents in the blood-to-luminal direction, serving as a secretory detoxification and as a part of the absorption barrier in the intestine [54, 55].

### 2.5 Low Solubility

For certain proteins with low solubility such as human growth hormone (18 mg/ml), poor absorption was believed to be a major cause for the low solubility. In an attempt to improve the solubility-limited bioavailability associated with these types of compounds, formulators have turned to the use of lipid excipients in which the compounds can be solubilized prior to oral administration. For selection of lipid-based delivery, the Biopharmaceutical Classification System (BCS) can serve as a useful preliminary guide [56]. Further elucidation of the physiological aspects of lipid excipients, for instance, the inhibition of gut wall efflux mediated by multidrug-resistant (MDR) P-gp and presystemic metabolism by CYP3A4 bound to the gut wall, can be expected to define further candidate selection based on the BCS [36, 37, 56]. Nanocapsules and nanoparticulates could help protein molecules to bypass the limited solubility, thus penetration and proteolytic barriers, by taking up the epithelial mucosa via the paracellular pathway [13].

### 2.6 Molecular Size

In particular peptides and proteins displaying a molecular size greater than 30 kDa, the intestinal membrane becomes an important rate-limiting factor for drug

absorption [57, 58]. Size limitation for protein drug oral absorption could be modulated by a formulation type and an absorption site. The particle sizes employed for current protein oral delivery can be classified into two: 10–1000 nm of nanoparticle and 1–1000 μm of microparticulates [10]. The uptake of particles within the intestine increases with decreasing particle size and increasing hydrophobicity [8]. Furthermore, this size dependency in absorption could be site dependent. One study, which employed a series of polyethylene glycols (PEG), suggests that a compound with a molecular weight up to 4000 Da might be significantly absorbed [42], assuming appropriate partition behavior and stability. However, several reports on insulin [human growth hormone (hGH); erythropoietin (EPO), and interferon (IFN)] and many other proteins with a molecular weight ranging from 6 to 30 kDa showed absorption when administered orally, indicating site-dependent absorption [59]. These findings may need further clarification.

### 2.7 Chemical Stability

Physical properties of proteins often present significant formulation problems not encountered with conventional organic drug molecules [3], for example, self-aggregation. The tendency of insulin to form hexamers is well known, and the absorption of hexamers is different than that of the monomer. Human calcitonin is also known for self-organization into fibrillar structures with reduced biological activity [60].

### 2.8 Drug Interaction

Drug interactions can occur at any step from absorption to elimination of a drug and can induce adverse as well as beneficial effects [61]. The main potential for drug interaction is with drugs or compounds that are metabolized by or affect CYP3A4, including imidazoles, grapefruit juice, erythromycin, mibefradil, and others [62]. Glutathione may play an important role in the inactivation of orally given peptides and proteins by thiol-disulfide exchange reactions [63].

### 2.9 Gender Difference

Gender-specific differences can be explained by differences in body composition between men and women and/or physiological changes during the menstrual cycle as well as differences in plasma protein binding secondary to hormonal characteristics [64]. In addition, gender differences in drug metabolism may be involved in the higher incidence of adverse reactions in women compared with men [65]. However, it has not been fully elucidated in the literature whether there is any quantitative and or qualitative difference in proteolytic enzymes and physiology of the absorptive cells in the intestine, which may produce a significant impact on protein drug oral absorption. Gender–related differences could be shown in phase I (cytochrome P450) as well as phase II (especially glucuronidation) reactions [66]. Frequent and sometimes clinically relevant gender differences could be identified for drug elimination processes and were predominantly linked to the gender–specific expression of metabolic enzyme systems, for example, CYP3A4 and CYPlA2. With regard to pharmacodynamics (PD), gender differences have been observed in baseline characteristics as well as in drug response, which might both, at least in part, be the consequence of modulation by sex hormones. Since most protein drugs are from endogenous sources, it would be important to understand baseline pharmacodynamics in oral drug delivery. Some of the most striking examples identified were in pain therapy and perception, glucose management, and arrhythmia susceptibility. CYP3A4, responsible for the metabolism of over 50% of therapeutic drugs, exhibits higher activity in women than in men [67], whereas the activity of many other systems involved in drug metabolism may be higher in men than in women [65]. Women and men also show different PD responses to a variety of drugs. While the clinical significance of these gender differences remains to be determined, it is anticipated to be most important in the administration of drugs that have a narrow therapeutic range.

### 2.10 Others

Particle uptake seems to be greater in older animals [10]. The exact mechanism of this was not fully explained. The presence of food seems to be another enhancing factor for particle uptake possible by increasing intestinal transit time. Hepatic insufficiency reduce the plasma clearance of a number of drugs eliminated by biotransformation and/or biliary excretion, but it can also affect plasma protein binding, which in turn could influence the processes of distribution and elimination [68]. In addition, reduced liver blood flow in patients with chronic disease will decrease the systemic clearance of flow-limited (high extraction) drugs, and portal-systemic shunting may substantially reduce their presystemic elimination (first-pass effect) following oral administration. When selecting a drug and its dosage regimen for a patient with liver disease, additional considerations such as altered pharmacodynamics and impaired renal excretion (hepatorenal syndrome) of drugs and metabolites should also be taken into account.

Consequently, dosage reduction is necessary for many drugs administered to patients with chronic

liver disease such as liver cirrhosis. Protein drug pharmacokinetics (PK) are not appreciably affected by age, gender, or race when differences in renal function and body mass and composition are taken into account [10, 12].

## 3 APPROACHES FOR ORAL DELIVERY

The strategy employing enzyme inhibitor(s) and absorption enhancers to protect from the various enzymes and to help to overcome its own hurdles, that is, hydrophilicity, molecular size, charge, and the like, seems to be the most popular approach for protein oral delivery [40]. Second, realistic approach could be modifying protein structures to more stable analogs by chemical synthesis. Targeting the specific absorption site and dosage form modification, that is, lipid vesicles, colloidal carrier systems with and without mucoadhesive polymers could be another approachs to improve protein absorption. A novel and perhaps less complex oral protein drug technology could be based on a combination of several approaches that are described below.

### 3.1 Enzyme Inhibiton

Due to the nature of enzyme distribution and quantities, the use of only enzyme inhibitor(s) for protein oral delivery will be extremely inefficient. However, some successful results have been reported for insulin administered with sodium glycocholate, camostat mesilate, and bacitracin to rats by Yamamato et al. [69] and with FK-448 and other protease inhibitors by other investigators [57, 70]. The CYP3A4 inhibitor showed marked increase in the oral bioavailability of cyclosporin [71]. To investigate the possible use of casein as an adjuvant for oral delivery of peptide drugs, the inhibitory activity of casein on proteases in rat small intestine was examined [72]. Utilization of both inhibitor cocktails and a specific absorption site with less enzyme distribution showed improvement in the absorption of large peptides, cholecystokinin and enkephalin analogs [34, 73], and protein drugs [35].

A new and interesting possibility for protein drug oral delivery makes use of a polymer and enzyme inhibitor conjugate system [74, 75] in which the embedded therapeutic agent is protected from enzymatic degradation [76]. The covalent attachment of aprotinin to chitosan exhibit mucoadhesive properties, which allows a drug release at the same intestinal segment as the protease inhibition takes place. Contrary, coadministered unbound inhibitors are highly diluted during GI passage, and, therefore, high amounts of the inhibitor are necessary in order to achieve an improved drug uptake [77]. Chitosan and its derivatives showed multiple effects of enhancer, enzyme inhibitor, and mucoadhesion to improve the absorption of insulin, calcitonin, and buserelin following oral administration [58]. Several ovomucoid species effectively stabilize salmon calcitonin (sCT) against serine proteases [78].

In similar work, the enzyme inhibitor, pepstatin analogs [79], were covalently joined to mucoadhesive polymers so that the inhibitor molecules were freely accessible to the enzyme as a substrate. This system provided advantages toward increasing contact time with the GI mucosa and maintained a controlled and sustained drug release from the adhered polymer and reducing unwanted toxic effects of the inhibitor because of its attachment to the nonabsorbable polymer backbone. However, from a practical point of view, the utility of this approach may be limited by high manufacturing cost [59].

### 3.2 Carrier Holecules or Enhancers

Avoiding temporary to long-lasting membrane damage, carrier molecules or enhancers improving the epithelial cell permeability of protein drugs were synthesized by Leone-Bay et al. [59, 80], which were low-molecular-weight, peptide-like compounds that interact covalently with the protein drug. This approach was successful for hGH oral absorption with a mean peak concentration of 55 ng/mL in primates [80]. Another group's research employing the delivery agent resulted in the bioavailability increase of 50–104% for hGH, interferon-α-2b, and insulin [81]. Permeability increases in the presence of carrier molecules for hGH, IFN, and insulin were 0, 350, and 800%, respectively, indicating a proportional increase of bioavailability to permeability [81]. The ability to increase oral absorption of granulocyte colony–stimulating factor (G-CSF) and EPO by covalent coupling to vitamin $B_{12}$ has been investigated [82, 83]. This absorption occurs via receptor-mediated endocytosis, and an essential requirement is the presence of the intrinsic factor of a mucoprotein.

The mucoprotein complex reaches the ileum, where resorption is mediated by specific receptors. Possible disadvantages of the vitamin-$B_{12}$-mediated delivery are the limited capacity of this active transport mechanism and the interference with vitamin $B_{12}$ absorption in chronic therapy [84].

The conjugated carrier of oligomeric transferrin (Tf) to insulin causes a 6- to 10-fold increase of the stability of insulin against chymotrypsin digestion [85]. Oral route of mini-proinsulin-transgenic *Ganoderma lucidum* can be effective in reducing blood glucose level less than or equal to 64% in 80% of diabetic rats [86].

### 3.3 Prodrugs and Analogs

Altering physicochemical properties of protein drugs seems to be the easiest approach [14, 87], warranting unaltered or intensified efficacy, although it requires the synthesis of a new chemical entity [59]. Changes can be made in lipophilicity, charge, molecular size, solubility, configuration, isoelectric point, chemical stability, enzyme liability, and affinity to carriers to enhance the absorption and systemic circulation. Two specific approaches made for peptide oral delivery by Samanen et al. [87]—the chemical modification of peptide amide bond to enhance intestinal permeability and the design of compounds bearing nonpeptide templates—were more amenable to the discovery of compounds with oral activity, from peptide pharmacophore models, for example, SB 208651 designed from the peptides SK&F 106760 and SK&F 107260. Computational modification of hGH attempts to improve its thermostability and oral absorption [88]. The permeability of 10 amino-acid ester prodrugs of levovirin (LVV) is increased [6.9-fold increase of the area under the curve (AUC) in Caco-2 cells [89].

### 3.4 Optimal Absorption Site

Many investigators [13, 90] suggested that identification of the optimal absorption site for a given peptide or protein is the first step toward the design of a delivery system that maximizes absorption. Regional variations in the penetration barriers to peptides may result in regional differences in their absorption. For instance, M cells located on the dome epitheliam of gut-associated lymphoid tissue are known to be capable of sampling macromolecular antigens from the ileum through an endocytotic pathway [91]. Controlling the absorption site to deliver proteins and large peptide drugs has been attempted with some success in improving oral bioavailability [34, 35, 73]. Researchers searched for absorption sites with less enzyme distribution and avoiding the hepatic first-pass effect and found, thus far, the oral cavity (buccal) and colon as alternative sites for protein oral delivery.

### 3.5 Buccal Delivery

The oral mucosa has greater permeability and perfusion than the skin while the oral cavity provides an environment almost free from the acidity and protease activity encountered elsewhere in the GI tract [92]. In addition, blood vessels of the oral mucosa drain directly into the jugular vein, avoiding first-pass extraction by the liver. Buccal delivery permits easy removal in the event of adverse reactions. Recent study revealed the presence of aminopetidase activity on the buccal mucosa and its inhibition by enzyme inhibitors [93]. Complete review on the regional variation in oral mucosal drug permeability written by Kurosaki and Kimura [94] is available. In this report, the structure and composition of the mucosa at different sites in the GI tract, factors affecting mucosal permeability, and formulation factors including penetration enhancement relevant to the design of systems targeting oral mucosal delivery were reviewed. Many oral mucosal delivery systems for numerous peptide/protein drugs have been described since the first attempt at a bioadhesive system by Nagai in the early 1980s [95]. Interactions of randomly methylated β–cyclodextrin (RAMEB) with buccal mucosa could be diffused through cell layers by paracellular pathway. Two and 5% RAMEB do not induce tissue damages even after 5 days [96].

Pituitary adenylate cyclase-activating polypeptide (PACAP) with the thiolated polymer chitosan combined with GSH and the nonionic polyoxyethylene surfactant Brij 35 led to an absolute bioavailability of 1% by the buccal route of porcine [97] α-interferon. With 5% lysalbinic acid, a product of the alkaline hydrolysis of egg albumin and a mild detergent, resulted in a five-fold increase in permeability through the mucous in 10 min, whereas, lysalbinic acid at a concentration of 0.3% increased buccal permeability of fluorescein isothiocyanate-labeled insulin (FITC-insulin) for above five times just in 10 min [98]. A relative bioavailability of $43.8 \pm 10.9\%$ was achieved after buccal application of sCT-loaded thin-film composites (TFCs) in rabbits [99].

Transforming growth factor β3 (TGF-53) has shown that it can temporarily arrest oral mucosal basal cell proliferation [100]. Delivery of calcitonin, LHRH, and glucagon-like peptide-I as an adhesive tablet showed the bioavailability of 37% [101], 100% [102], and 41% [103], respectively. Exciting challenges remain to influence the bioavailability of drugs across the oral mucosa. Nonetheless, there are still many issues to resolve before this effective and convenient route of drug delivery can be thoroughly and safely utilized [92].

### 3.6 Colon Delivery

A common belief is that colonic delivery for orally administered protein drugs is possible because of the postulated low proteolysis activity in the large intestine, an assumption that requires further verification [104]. Yet, other opportunities for colonic delivery of drugs also exist. Some recent examples include bypassing small intestine metabolism, achieving constant absorption rates for some molecules, and delivering cationized antioxidant enzymes to the colonic epithelium. Colonic delivery of insulin after coating with azo-cross-linked copolymer of styrene and hydroxyethyl methacrylate(HEMA), aiming for activation by micro-

flora of large intestine and intestinal delivery of enterocoated cyclosporin, are examples of site-specific delivery cases [13, 105, 106]. Colon-specific drug delivery systems (CDDSs) have been investigated for model drugs, bovine serum albumin (BSA) with resistant starch-coated films [107, 108], and bee venom peptide with calcium-coated alginate-gel-beads-entrapped liposome [109].

Baluom et al. [110] also achieved about 15% of bioavailability after colonic administration of sCT using submicron emulsions containing Carbopol 940. Another problem with protein delivery to the colon is various transit times; ranging from a few hours to 10 h [111]. Thiamine-coated nanoparticles showed a strong capacity to be captured in Peyer's patch of rat colon by fluorescence microscopy images [112].

### 3.7 Targeting Transporter

Recent advances in gene cloning [113], molecular biology techniques, and computational methods [114] make it possible to study the characteristics and distribution of transporters [115] at the molecular level based on molecular characterizations of membrane transporters and accumulated biochemical data on their specificities and kinetics [113], structural modification [116], and targeting of a specific transporter is a promising strategy for the design of drugs that improve bioavailability and tissue distribution [37, 117].

The peptide transporter is limited to peptides of less than 4 amino acids [82]. Its physiological and pathophysiological conditions are reviewed by Nielsen and Brodin [118]. The bile acid transporter is limited to peptides of less than 400 Da moleadar weight (HW), while the vitamin $B_{12}$ transporter is limited to pharmaceuticals that require less than 40 mol per day.

### 3.8 Colloidal Carrier Systems

Various colloidal systems have been studied for absorption enhancement of proteins, such as submicron emulsions [108, 119], lipid suspensions, liposome, polymeric nano/microparticles, and freeze-dried suspension [120].

The bioavailability of a stable self-emulsifying formulation for insulin is up to 15.2% at an oral dose of 2.5 IU/kg in comparison with the hypoglycemic effect of native insulin (0.5 IU/kg) delivered by subcutaneous injection in diabetic beagle dog [121].

Controversy still exists on physicochemical factors governing gastrointestinal uptake, including size, size distribution, consistency, hydrophobicity, and surface properties [84]. Prolonged contact of nanoparticles (NP) with absorptive cells may be achieved using bioadhesive materials. Bioadhesion could be followed by NP uptake in a second step. Therefore, biomaterials with both adhesive and protective properties would be desirable for oral protein delivery in order to assure the drug stability and thus improved bioavailability [122].

### 3.9 Nanoparticles

Nanoparticles, defined as solid particles with a size in the range of 10–1000 nm, allow encapsulation of the protein drugs inside a matrix, protecting them against enzymatic and hydrolytic degradation. Various biomaterials of polymers, lipids, lectins, and the like could be employed to make NP using techniques of emulsion polymerization, interfacial polymerization, emulsification evaporation, solvent displacement [123, 124], salting out, emulsification diffusion, and desolvation [125, 126]. The solvent displacement and salting out have received increasing importance because they provide less stress to protein drugs. The physicochemical properties of NP, for example, portion of the mucoadhesive polymers [127] and their behavior on exposure to physiological media, for example, formulation pH [128], are greatly dominated by their chemical structures and surface characteristics [84, 129, 130]. The mucus layer and Peyer's patches [131] were considered to be uptake sites for NPs. Nauoparticles and cyclodextrins are biocompatibility as delivery systems [132]. The PEGylation of chitosan reduced the cytotoxicity of the nanocapsules [123]. Studies on the novel formulation of alginate-blended chitosan NPs have been made to improve the controlled release [133, 134] and try to optimize the alginate : chitosan mass ratio [135].

Surface compositions of NPs that greatly dominate the intensity and stability of the response are newly developed by using glucomannan-coated chitosan [136], chitosan-coated lipid [137, 138], NP film consisting of carboxylation chitosan-grafted nanoparticles (CCGNs), bilaminated films [139], and Polydextran aldehyde with particle core [140]. Some peptides such as helodermin confirm the high permeability of the NP system across in vitro follicle-associated epithelium model [141].

Erythropoietin loaded short fiber length carbon nanotubes deliver more EPO and absorption enhancer to the absorptive cells of the rat small intestine [142]. The structural integrity of insulin after being entrapped into chitosan/alginate nanoparticles produced by ionotropic polyelectrolyte pre-gelation was preserved as a result of assessment by Fourier transform infrared (FTIR) and circular dichroism (CD) [143].

### 3.10 Bio(muco)adhesion

Mucoadhesive oral drug delivery systems have received considerable attention over the last decade. Utilizing bioadhesive polymers to prolong and/or to intensify the

contact between controlled-release dosage forms and the stomach or gut mucosa has also shed new light on the potential of mucoadhesive polymers. In a series of cationic, anionic, and neutral polymers, anionic poly(acrylic acid) (PAA) was found by Park and Robinson [144]. Poly(methacrylic acid) grafted–poly(ethylene glycol) (MAA-*g*-EG) hydrogels [145] show the highest mucoadhesive characteristic. PAA could be identified as a potent inhibitor of proteolytic enzymes as well. There is also increasing evidence that the interaction between various types of bio(muco) adhesive polymers and epithelial cells has direct influence on the permeability of mucosal epithelia. By choice of polymer concentration and, more importantly, solvent type, organogels exhibited a wide range of viscoelastic and flow properties [108].

It was demonstrated that the adhesion or binding of proteins to the intestinal epithelial cell surface led to enhanced uptake by nonspecific receptor-mediated endocytosis [146]. One area to improve this technology is to increase the localization or retention in any desired regions [13]. The inability of mucoadhesive systems to remain for longer periods at the site of attachment is partly due to the high turnover and sloughing rates of the mucus to which the system attached (40–270 min) in rats [147] and partly due to the possible displacement of the delivery system from binding to the mucus layer by soluble mucus in the luminal contents [148]. Rather than being just adhesives, mucoadhesive polymers may, therefore, be considered as a novel class of multifunctional macromolecules with a number of desirable properties for their use as biologically active drug delivery adjuvant [40]. Novel bioadhesives allow for the capacity of the enhanced adhesion along with sitespecific ligands such as lectins [149–152], RGD peptides [153], and immunoregulatory properties with lectins [150, 154–156].

Mucoadhesive tablets are examined using Carbopol 974P, Labrasol, for EPO [157]. Microfabrication technology combined with appropriate surface chemistry may offer the highly localized or unidirectional release of drugs, permeation enhancers, and promoters [152, 158].

### 3.11 Liposomes

Liposomes have been abandoned due to insufficient stability under in vivo condition [8]. In an application to vaccines, homogeneous unilamellar liposomes of ~100 nm were reported to be taken up into M cells [159]. However, studies on the vaccine liposome led to the overall conclusion that liposomes are ineffective as adjuvants for the nonparticulate, naturally weak immunogens used in the investigation. A mucoadhesive liposomal system prepared by coating a negatively (phosphatidyl choline) or positively charged (salicylic acid) liposome suspension with mucoadhesive polymer solutions, such as chitosan and carbopol, showed some success in significant absorption of protein drugs, for example, insulin and calicitonin [160]. Chitosan-coated liposomes [161, 162], polysaccharide-coated liposomes [163], and PEG-coated liposomes [164] were characterized by the mucoadhesiveness of liposomes and resultant pharmacological effects of the liposomal protein and/or peptide drug.

Recently, the liposome technology has been revisited [165] and evaluated. Various cytokines in liposomes [166] and multivesicular liposomes characterized by their unique structure of multiple nonconcentric aqueous chambers surrounded by a network lipid [167] have been tested and obtained satisfied pharmacodynamic effects of model protein drugs.

Oral delivery of antigens in liposomes modulates oral tolerance to the antigens [168].

A combination assay of PAMPA and unidirectional (apical to basal) Caco-2 permeability model can synergistically provide invaluable permeability/absorption assessment of liposomal formulations of serratiopeptidase [169].

Because of a liposome's instability, alternative nonionic surfactants vesicles, "niosomes," have been investigated. Using this technique, it has been synthesized and examined for delivery of insulin [170] and adjuvant carrier system [171].

### 3.12 Microencapsulation

Poly(lactide1gycolic acid) (PLGA) polyester microspheres have been used for long-acting injectable sustained-release formulations of protein drugs [172] due to its biodegradable and biocompatible property. PLGA microparticles separated from the magnetic material are providing an opportunity for long-term efficacy and high bioavailability of orally delivered protein drugs [173, 174].

This PLGA microsphere has also been investigated as a potential antigen delivery system for oral vaccines of staphylococcal enterotoxin B (SEB) [175]. Viruses were also successfully encapsulated in PLGA microspheres for oral delivery [176]. Zein, one of the typical prolamines and a major storage protein of corn [177, 178], is insoluble in aqueous media yet is degraded over time by protease enzymes to constituent peptides and amino acids showing mucoadhesive properties. Alkermes, Inc. (Cambridge, MA) was used successfully to encapsulate calcitonin, EPO, sesmopressin, vasopressin, and insulin into the zein microsphere system for oral administration [159].

Because of different compositions [179, 180], additives of microparticles [181] influence the degree of releasing drugs. PEGylated insulin undergoes about 10% degradation with elastase, while native insulin undergoes about 70% degradation after 1 h incubation [182].

Calcium phosphate particles containing insulin keep from degradation while passing through the acidic environment of the GI track until being released in the less acidic environment of the intestines [183]. Serratiopeptidase (STP)-loaded nanocore was further encapsulated into alginate gel for enzyme protection [184].

### 3.13 Emulsions

Using this technology the method of transport in the gastrointestinal mucosa was shown to be transcellular by enhancing membrane permeability with oil in the formulation [185]. The ability of water-in-oil (W/O) emulsion containing ovalbumin (OVA), a model antigen, efficiently enhances the induction of Th2-dominated imbalance [186].

Calcitonin and hGH in microemulsion for an oral formulation had been developed and tested in humans for commercialization by Cortecs Int. Ltd. (Middlesex, UK) and Affinity Biotech, Inc. (Aston, PA) [159, 187].

### 3.14 Inclusion/Association Complexes

Dextran-derived biomaterials have been considered to be compatible matrices for protein and bioactive drugs because of their hydrophilic properties and ability to control drug dissolution and permeability. Cyclodextrins (CD) are potential candidates for use as delivery systems because of no effect of antigenicity, tolerogenicity, or immunogenicity [188].

Protection of the peptide by complex formation with α-cyclodextrin was also studied with respect to their ability to protect the peptide against proteolytic degradation by the exopeptidase, γ-glutamyl transpeptidase [189]. Cyclodextrin–insulin complex encapsulated PMAA–based NPs are examples of satisfied pharmacodynamic effects of model protein drugs [190].

### 3.15 Gastrointestinal Patch Systems

The use of a multilayered patch system is proposed to induce greater levels of absorption and stability at the intestinal epithelium. Patches comprise layers of thin, flexible membranes: an impermeable backing, a drug reservoir, a rate-controlling membrane, and an adhesive [191]. The pharmacological availability of model drugs in a multilayered patch system, for example, insulin [192], human G-CSF [193], interferon-α (IFN-α) [194], and EPO [195] had been tested.

### 3.16 Hydrogels

A hydrogel is a network of hydrophilic polymers that can swell in water and hold a large amount of water while maintaining its structure [196]. Hydrogel is sensitive and responsive to environmental variables. Thus, a pH-sensitive hydrogel is the practical application for delayed-release systems. The total amount of the drugs released should be determined to compare the rate between erosion rate and release rate [197]. Poly(2-hydroxyethyl methacrylate) (PHEMA) hydrogels can modify drug release profiles, reducing the early burst effect [198] and can make layers together with poly(methyacrylic acid) (PMAA), resulting in unidirectional release [199]. Encapsulation of cross-linked subtilisin microcrystals in hydrogel beads is used for controlled-release applications [200]. Dual cross-linkage effectively promoted the stability of beads under gastrointestinal tract conditions [26, 201].

Complexation hydrogels assessed transport-enhancing effects on the insulin-loaded polymer [202–204]. The oral administration of insulin using pH-responsive hydrogels has a similar effect on subcutaneous delivery [205, 206].

A series of poly[methacrylic acid-grafted-poly(ethylene glycol)] [P(MAA-*g*-EG)] with different polymer compositions are newly designed complexation hydrogels [207–209].

In addition, a hydrogel group of superporous hydrogels (SPH) and SPH composite (SPHC) have also been developed for prolonging the residence time of delivery systems in the GI tract with a new mechanism of action [210]. rhEGF loaded on Eudispert hv (poly(ethylacrylate/methacrylic acid) 50:50) hydrogel with sodium lauryl sulfate (SLS) prolongs the release from the formulation at the site of action [211].

### 3.17 Lipidization

The lipidization strategy involves the addition of lipid-like molecules through the modification of the hydrophilic moieties on the drug structure. [212]. The AUC of oral fatty acid–polypeptide conjugation of sCT was at least 19 times higher than that of sCT [213].

### 3.18 Oral Vaccination

Currently, the oral vaccine formulations approved by the Food and Drug Administration (FDA) are enteric coated adenovirus tablets, typhoid fever bacteria in gelatin capsules, polio virus in liquid, and the lyophilized rotavirus [214]. The successful use of live attenuated

viral and bacterial vaccines depends not only on the proper choice and delivery of the microorganisms but also on maintaining the sufficient potency required for an immune response [215]. *Lactobacillus* is utilized as a potent oral vaccine carrier. Vaccination purposes have been obtained with tetanus toxin fragment C (TTFC) as the model antigen [216]. De Jonge et al., [217] use an amorphous inulin matrix as a stabilizer to generate influenza virosomes as a stable freeze-dry (lyophilization) powder formulation. The living rate of engineered yeasts secreting active compounds directly in the digestive tract is more than 80% [218] and the effects of using cryoprotectants on them were assessed by an artificial digestive system [219]. The effective delivery of antigens via the oral route is an extremely desirable goal. Mucosal delivery of antigens stimulates mucosal and systemic immunity without affecting maternal antibodies and reduces the need for sterile needles or trained personnel [220].

Two of the most promising potential approaches for oral vaccination are the use of lectins [221] to target vaccines to the epithelium and the association of vaccines with biodegradable microparticles [217, 222–229]. Attending to the need for new vaccine adjuvants, a highly stable cochleate structure from Proteoliposomes is suggested for antimeningococcal vaccination [230]. Lipid vesicles containing bile salts (Bilosome) can successfully induce systemic and mucosal immune responses, characterized by IgG and IgA antibodies, respectively. [231–233]

## 4 FUTURE WORK

### 4.1 Vitamin $B_{12}$ Conjugates

Vitamin $B_{12}$ conjugates to deliver protein drugs (e.g., G-CSF, EPO, and insulin) by the oral route have been pursued by a few investigators [82, 83, 234]. This system relies upon the natural uptake mechanism for vitamin $B_{12}$ to co-transport peptides and proteins linked to the vitamin $B_{12}$, from the intestine to the circulatory system. In an exciting extension of the technology, it has been found that it is also possible to transport nanoparticles, linked to the vitamin $B_{12}$, into the circulatory system. Such nanoparticles can potentially be loaded with peptides or proteins of choice, and so protect these molecules from degradation in the intestine, while simultaneously transporting them into the circulatory system.

### 4.2 Potent Inhibitors/Enhancers

Ideal protease inhibitors are effective at preventing or suppressing enzymatic degradation in the intestine. Bowman-Birk inhibitor (BBI) is a protein with a molecular weight of 8000 Da with a well-characterized ability to inhibit trypsin and chymotrypsin [235, 236]. Developing reversal agents for P-gp, which can substantially increase oral absorption [237], could be an alternate approach to aid the inhibitor strategy. Promising strategy would be the use of polymeric inhibitors because they would offer the advantage of remaining more concentrated in the GI tract at the site of drug absorption and of not being absorbed per se, thus avoiding systemic toxic side effects [238]. Enhanced mucoadhesive properties of thiolated chitosan increase the inhibition of P-gp substrates [238, 239], pharmacological efficacy of insulin [240], and pharmacological efficacy of sCT [241].

### 4.3 Assay Development

An increased understanding of the many factors that can alter the analysis and pharmacokinetics of protein drugs and the development of simple yet sensitive and specific analysis methods are essential for protein drug oral delivery. Enzyme-linked immunosorbent assays (ELISA) have become the most common method of detection, and commercial kits are available for a wide variety of protein drugs. Monoclonal antibody products are sensitive, have minimal cross-reactivity, and are relatively inexpensive when compared with high-performance liquid chromatography (HPLC). However, the primary limitation of these assays is their inability to measure biologically active proteins. Conversely, bioassays do measure a biological event, that is, proliferation or cytotoxicity but are generally not used because of their high cost, long assay completion time, lack of specificity, poor sensitivity, and influence of environmental conditions on the outcome.

## 5 CONCLUDING REMARKS

The GI enzymatic barrier for protein oral delivery is formidable. Overcoming this barrier is one of the technical challenges for the pharmaceutical scientist. Other obstacles associated with protein oral delivery remain challenging as well. However, significant progress has been made with each of the obstacles and with certain proteins. The development of the composite formulation, which improves bioavailability yet meets regulatory requirements for reproducibility and intra and intersubject variability, and reasonable manufacturing costs, will be difficult, but the future of this infant field is bright.
